PATHOLOGICAL ANATOMY.—The earliest sign is increased vascularity of the coils of the small intestine; the peritoneum covering them is apparently more readily attacked than that over the large gut. Almost synchronously with this vascularity the intestine begins to dilate, and when this dilatation becomes extreme, we have the condition termed *tympanites*. As the distension increases the coils become pressed together in lines more or less parallel with the long axis of the bowel. The vascular dilatation, which at first is uniform, becomes more marked along the lines of least pressure, which is usually in the triangular space where three coils meet. At this stage the peritoneal fluid is diminished, being absorbed probably by the enormously dilated capillaries and veins, so that the surface of the gut may still be shiny, although it is distinctly dry.

This condition so far is present in all cases, and it depends upon the further progress of the inflammation what the ultimate condition may be. Broadly speaking, the subsequent inflammation produces one of three conditions.

1. *Adhesive or dry peritonitis.*—The peritoneal fluid is absorbed owing to the enormous dilatation of the vessels, and when inflammatory exudation is poured out the fluid part is absorbed, leaving masses of solid exudation matting the coils together. In cases that resolve quickly this lymph soon organises or may become to a large extent removed by wandering cells from the peritoneum. If present in considerable amount, adjacent coils are temporarily united together; but the constant peristalsis gradually stretches the adhesions, which may finally break loose at one end. It is remarkable how quickly these adhesions disappear, a fact which surgeons often have an opportunity of observing on performing a second operation upon the abdomen. It is seldom that more than one adhesion exists; hence the curious phrase 'the solitary band of Gay,' so called after the surgeon who first described these bands and who pointed out how they were as a rule found single. When the exciting agent relaxes its activity slowly the enormous masses of adhesions which result may so distort the relative position of the viscera as to justify the term *peritonitis deformans*. The writer is inclined to believe, however, that these cases are of slow formation from the first and are really examples of chronic peritonitis.

2. *Serous.*—Here we find that there is a definite exudation of serum in addition to the 'lymph.' The amount of this fluid may be quite small or may reach the proportions of a good-sized ascites. Like all inflammatory exudations, its appearance varies in proportion to the intensity of the inflammation from a richly blood-stained to a clear liquid. This condition is more often met with in chronic peritonitis. See p. 1201.

3. *Suppurative.*—There is no sharp line of demarcation between the turbid serum of the former variety and the kind of fluid which is sufficiently opaque to deserve the term 'pus.' It is often difficult to decide whether to call the exudation 'turbid serum' or 'pus.'

PATHOLOGICAL HISTOLOGY.—In the acute stage of peritonitis the inflammation as seen through the microscope differs in no respect from acute inflammation elsewhere. The classical descriptions of early inflammation could be accurately applied to peritonitis. A good many experimental studies have been made of the minute changes in peritonitis. Some observers state that the endothelial cells of the serous membrane play a definite part in the inflammatory processes; that they proliferate in considerable numbers; that they pass into cubical and spindle stages, and into large granulation cells, and that they take the chief part in the formation of new tissue; in other words, fibroblasts are looked upon as descendants of proliferated endothelial cells. On the other hand, other observers are strongly convinced that the new tissue is derived from connective-tissue cells already existing just beneath the pavement-cells, and that the adhesions are formed solely from these sub-epithelial cells, the pavement-cells being destroyed in the process of inflammation.

SYMPTOMS.—When we consider the numerous causes of acute peritonitis it is not surprising that symptoms vary exceedingly in different cases. Sometimes we are confronted with a patient whose appearance suggests typical surgical shock; in another case the local evidences of peritonitis are at once obvious; in yet a third the symptoms generally may be so masked that the most experienced clinician may miss the fact that the central feature of the case is peritonitis. There is no definite line of demarcation between those cases which die within twenty-four hours with symptoms of general saphæmia, and those in which the peritoneal symptoms form so prominent a feature that attention may be withdrawn from the fact that the patient is also suffering from the effects of general septic poisoning. The great majority of cases in which the peritoneum is inflamed present, at first, symptoms strongly suggestive of general peritonitis; yet after a day or two it is quite obvious that the case is one of local inflammation. This class of case is especially met with in cases of appendicitis and salpingitis. Many authorities consider that in these cases the general peritoneum is inflamed at first, but that its protective mechanism has checked the onslaught of the micro-organisms except at the local spot where the headquarters of the germ are situated. In the opinion of the writer the following two cases afford reasons for believing that this is not the only explanation. In each case the patient was a girl eighteen years of age, presenting no previous trouble except a recently developed anæmia; each was taken ill suddenly with marked abdominal pain of the 'doubling up' character, associated with vomiting; in each case there was excessive rigidity and quiescence of the abdominal wall, and in each case pain was complained of chiefly in the epigastrium. One patient had passed on the day preceding and on the morning of the attack a copious stool containing altered blood. The diagnosis of a ruptured gastric ulcer was considered the most likely one. In each patient a median exploratory incision was made above the umbilicus and the whole upper abdomen examined carefully;

there was no sign of inflammation. In one case a second incision was made below the umbilicus, and again no evidence of any inflammation could be found in the abdominal or pelvic organs; there was some slight thickening in the right iliac fossa, and keeping in view the great probability of appendicitis, no attempt was made to pull the cæcum and appendix into view, but the wound was at once closed. On the sixth and eighth days respectively a large abscess in the right iliac fossa was opened. This obviously originated in the appendix. Both patients recovered. The clinical signs of apparent early general peritonitis in such cases as these are, in the opinion of the writer, due to the spread of reflex nervous action, as described in detail later in this article.

There are two classes of cases which may be taken as types of a general peritonitis, viz. that following operations upon the abdomen and that following an appendicitis where the micro-organisms get through the wall of the appendix without necessarily an actual perforation of the wall of the tube taking place. In other words, it may be a bacterial perforation only. The former cases are happily becoming more and more uncommon, and therefore it will be of greater use for us to consider the latter as forming the most common type of general peritonitis. There are the very acute cases before referred to in which the patient appears to be suffering from profound shock and poisoning. In another group of cases the symptoms of peritonitis are slight when compared with the mischief that is found at the operation or autopsy. These cases are termed *latent* or *masked* peritonitis.

A typical case of acute peritonitis.—On a certain day the patient begins to feel unwell; within an hour or two he is cold and may shiver; fairly often there is an actual rigor ushering in the symptoms. The first definite symptom that makes its appearance is nearly always pain which, though very constant in its presence, is very variable in its character and in intensity. This pain, when slight in degree, has the peculiar quality of worrying the patient out of all proportion to its intensity, and confers upon the face a characteristic expression of anxiety. On the other hand, the actual intensity of the pain may be so great that it is quite alarming both to the patient and his friends. At first the pain is referred to the whole of the abdomen, but later on it is generally localised to the region of the umbilicus.

As a rule the abdomen is rigid, and the skin of the whole of or a part of the abdomen is markedly hyperæsthetic. In order to diminish the abdominal tension as much as possible the patient lies on his back with the thighs flexed and the shoulders raised, and later on in order to increase the 'vital capacity' of the thorax the arms may be raised above the head. Owing to this rigidity of the abdominal muscles the respirations become more and more costal in type. The pulse is increased in frequency, is of high tension and small; indeed, the tension is so considerable that this, together with the diminished size, has gained for it the term *wiry*. The temperature soon rises to 103° or 104° ; after the initial rise it keeps at an average of 101° to 102° .

After the first twenty-four hours the hard, somewhat retracted, abdomen becomes distended, and the percussion-note becomes increasingly tympanitic. Distension rapidly increases so that the abdomen

becomes blown out and tense. Vomiting usually sets in about the same time as the pain, and is a prominent feature of the disease. At first the ordinary stomach-contents are ejected; then the fluid is yellow, being distinctly bile-stained; and this is followed by a characteristic green vomit, which is finally succeeded by a brownish-black liquid having an offensive odour distinctly faecal in character. At the onset the bowels may be loose, but as soon as the abdomen distends constipation sets in. The act of micturition is often frequent at first, but later on there may be retention, especially if the origin of the trouble is in the appendix or in the pelvic organs. The urine is small in quantity and high-coloured, usually containing abundance of indican (p. 727).

When all the symptoms are fully developed the aspect of the patient is quite characteristic; so well was it described by Hippocrates that it is often termed '*facies Hippocratica*,' viz. 'a sharp nose, sunken eyeballs and hollow temples, the ears cold and pinched with their lobules turned outwards; the skin of the forehead is rough, puffy and dry; the colour of the whole face being brown, black, livid or leaden in colour'; this description requires modification only in the last statement, where we must remember that the face described belonged probably to the oriental type.

There is usually free fluid causing dulness in the flanks, which may shift on rotating the patient. This typical case of acute peritonitis usually lasts from five to ten days, nearly all the symptoms increasing in severity until the fatal end, which is usually heralded by the skin of the face and hands becoming cold and clammy and tinged with a dark blue colour.

The onset.—As a rule this is quite sudden, but the time relations of the onset are largely determined by the actual cause of the general invasion. If it is due to the perforation of the stomach, intestine or appendix, without any previous inflammation of the peritoneum, the onset comes with alarming suddenness. Within a minute the patient passes from a condition of apparent health to a condition of collapse and shock that has been known to end fatally within an hour.

In other cases where an organ, generally the appendix, has been inflamed for a long time the invasion of the general cavity is comparatively speaking gradual, and it may take twelve to twenty-four hours before it can be said that acute general peritonitis is definitely established. When very acute the onset is associated with a rapid fall in temperature; in other cases there may be a rigor and a temperature of 104° or 105° within an hour or two of the commencement of the attack.

Shock (Peritonism).—The shock produced by an extensive scald of the skin, or by the skin being badly lacerated, is extreme, and bears a very definite proportion to the area of skin involved. In the same way any extensive lesion of the peritoneum produces a similar condition, whether it be due to the irritation of the contents of the stomach, as in perforation of a gastric ulcer, internal strangulation, or the torsion of an ovarian pedicle.

Pain.—This is nearly always the earliest symptom, and may vary from a pain that is accurately described by the term '*agonising*' to a pain slight in intensity but of such a character that the aspect of the patient shows considerable anxiety, as mentioned above. At first the pain is generalised over

the whole abdomen, but later on it is usually referred by the patient to some definite area; very often the region of the umbilicus seems to be the most painful. In cases where inflammation of a definite organ has given rise to the peritonitis, the pain may be referred to the region of the affected organ, especially in the case of the appendix.

Tenderness.—This tenderness may be of two kinds—(1) *Superficial tenderness*, or hyperæsthesia of the skin; (2) *Deep tenderness*, which may reside in the muscles, peritoneum or underlying viscera (see p. 1146). When the superficial tenderness is very extensive it is probably associated with inflamed intestines. The deep tenderness, on the other hand, is due to the direct pressure upon the peritoneum, and is obtainable at any spot where the inflamed peritoneum can be pressed upon. In general peritonitis this deep tenderness, therefore, can be elicited practically over the whole of the abdomen, with the exception of the area posterior to a line drawn from the anterior superior iliac spine to the tip of the last rib, where it is not easy to press directly upon the peritoneum. In the early stages of general peritonitis the superficial tenderness is nearly always extremely well marked. On Head's hypothesis this would mean that the small intestines or some other of the viscera were distinctly affected, and this superficial tenderness would not necessarily be limited to the front of the abdomen, but there might be a band of hyperæsthesia running to the back or downwards towards the groin (see p. 1142). As the peritonitis is becoming established the superficial tenderness becomes much diminished, and may finally disappear, whereas the deep tenderness progressively increases until the general peritonitis is well developed. In nearly all cases of general peritonitis some organ of the abdomen is first affected, and this organ may continue to present its referred superficial tenderness after the general peritonitis has become established. In several cases of general peritonitis arising from appendicitis the writer has found an extensive area of superficial tenderness below the level of the umbilicus co-existing with the deep tenderness, and as the operation advanced general peritonitis has been found. On this point, therefore, we may make two positive assertions, namely, that if the tenderness is only superficial there is no marked affection of the peritoneum; and that in cases of undoubted suppurative peritonitis due to appendicitis there may be superficial tenderness existing at the same time as the deep.

Vomiting.—Next to pain this is the earliest, most constant, most distressing and most persistent symptom. The abdominal muscles take little if any part in the expulsive act, so that the stomach itself does most of the work; hence the act of vomiting appears to occur without much effort. In the early stages the vomiting is principally due to a poisoning of the centre in the medulla oblongata. After paralysis of the small gut has set in it much resembles the vomiting of intestinal obstruction.

Defecation.—During the early hours of the attack there is very often a stool which is generally described as being loose; diarrhoea is not uncommon. A frequent desire to defæcate without any result is sometimes met with, and this may be so intense as to deserve the term 'tenesmus.' As soon as the distension of the small gut sets in the colon becomes inert and constipation is the rule in the fully developed peritonitis.

Distension of the Abdomen (Meteorism).—As the intestinal coils become paralysed and distended, and the abdominal muscles begin to relax, we get the condition of meteorism, which gradually increases until the abdomen is much distended. This gradual distension of the abdomen is undoubtedly diagnostic of acute general peritonitis, and in the opinion of the writer it is a certain indication that no delay should be allowed before opening the abdomen.

Temperature.—This is the most variable symptom of all, so variable indeed that it is safer for the practitioner to place no importance whatever upon this symptom so far as any guidance concerning diagnosis and treatment is concerned. In the sudden perforation the temperature is usually subnormal and often remains so until the fatal termination.

METHOD OF EXAMINATION.—The patient should be placed on his back with the legs extended and the arms by the side of the body. The body is uncovered to such an extent as to show the apex-beat of the heart above and Poupart's ligament below. As the examination proceeds as much of the body should be covered up as is possible. The character and areas of tenderness should be carefully ascertained. For the details of the examination see ABDOMEN, Examination of.

The patient should always be examined *per rectum* or *per vaginam* to ascertain the condition of the pelvic organs.

CLINICAL VARIETIES.—*Peritonitis Fulminans; Ultra-acute peritonitis.*—In these cases, usually caused by the perforation of some part of the alimentary canal, in which no adhesions have formed from previous inflammation, the patient is suddenly seized with most acute pain and, within a few minutes, is suffering from the most profound shock. As the bacterial invasion proceeds symptoms of septic poisoning rapidly develop, and the patient dies within 24 to 48 hours without having rallied sufficiently for operative interference to be seriously entertained.

There is a group of cases following operation upon the abdomen, now happily becoming less and less common, in which the patient never really recovers from the shock of the operation, but dies within 24 to 48 hours with a rather distended abdomen. On *post-mortem* examination there is scarcely any evidence of inflammation of the peritoneum, certainly not enough to justify us in saying that the patient dies of peritonitis. Most surgeons consider they are justified in looking upon this result as death from shock, and consider that the intestinal distension is due to some special reflex nervous mechanism. Some pathologists, on the other hand, have found the peritoneal cavity to be infected with micro-organisms, and they look upon these cases as instances of a very rapid invasion of the peritoneum by virulent bacteria which grow so rapidly that inflammation has no time to develop. A definite series of accurate bacteriological investigations alone can settle this point.

Latent or masked peritonitis.—The patient walks into the hospital and does not feel particularly ill; he usually states that his illness commenced four or five days previously, but that until that particular day he was not ill enough to seek advice. Within two or three days he suddenly becomes collapsed and dies with his peritoneal cavity full of pus. Owing to the absence of urgent symptoms the

surgeon's help is often not summoned until the patient is too collapsed for operative interference to be anything more than a forlorn hope.

Peritonitis of the new-born child.—These cases are due to one of two causes: (1) the septic infection of the umbilical cord, due probably to faulty technique on the part of the accoucheur or midwife; (2) rupture of the distended large intestine, which may be due to the pressure of parturition, but more likely to the giving way of some small ulcer in the colon.

Peritonitis caused by cutaneous erysipelas.—In rare instances erysipelas of the abdominal wall has been followed by fatal peritonitis. This is difficult to explain because the lymphatics of the abdominal wall do not communicate with those of the peritoneum. The symptoms of the peritonitis are often masked and not even suspected during life.

Peritonitis in the course of acute specific fevers.—Peritonitis is most commonly met with in scarlet fever, as we might expect from the tendency of this disease to develop dangerous complications. In typhoid fever it may occur as the direct result of a perforating ulcer or be due to a bacterial penetration of the wall of the alimentary canal without any physical breach of continuity. Peritonitis has also been met with in the course of measles, small-pox, and typhus fever.

Rheumatic peritonitis.—Although doubt has often been thrown upon the existence of this complication of rheumatic fever, it is definitely proved that acute inflammation of the peritoneum does sometimes occur as a complication of acute rheumatic fever. It usually terminates favourably after a few days, although fatal cases have been reported.

Peritonitis in Bright's Disease.—This is a rare complication. The mode of origin of the peritonitis in this disease as in the case of acute rheumatic fever is possibly as follows: A purely chemical peritonitis is set up by toxins. After a time the wall of the intestine is sufficiently injured by this chemical peritonitis to allow the organisms contained in the intestinal contents to work their way through to the peritoneal cavity (p. 221).

Idiopathic or 'cryptogenetic' peritonitis.—The more carefully cases are examined by improved modern methods the rarer does the diagnosis of idiopathic peritonitis become. At present there are two groups of cases of which the origin is absolutely obscure, and hence it is convenient to place them under this heading. In the one group the patients are children, chiefly girls, and in the other the victims are adults. In both these groups a 'chill' is generally quoted as being the cause. The attacks of enteritis with diarrhoea so commonly met with in Europeans living in hot countries, especially in Egypt, seem to be due solely to some reflex vaso-motor disturbance from the sudden chilling of the body in an atmosphere nine times drier than the one they have been accustomed to. The cooling of the body by means of perspiration is therefore rapid, the atmosphere being very hygroscopic, so that a reflex effect is produced causing a dilatation of the vessels of the splanchnic area. If this condition is neglected it is easy to see how some inflamed area of the gut may prove a weak spot and allow the germs to penetrate to the peritoneal cavity.

DIAGNOSIS.—The following conditions may simulate peritonitis:—

1. *Acute intestinal catarrh (Enterocolitis), in*

which diarrhoea and intermittent colic are the chief symptoms.

2. *Intestinal obstruction.*—The differential diagnosis between peritonitis and this condition may be impossible for the first two days and sometimes throughout the disease. See pp. 774–787.

3. *Hysterical peritonitis.*—A condition met with on the Continent more frequently than in this country.

4. *Certain rare conditions*, such as acute hæmorrhagic pancreatitis, or a ruptured tubal pregnancy. See p. 1151, and PREGNANCY, Diseases of.

TREATMENT.—It is an admitted fact that an acute general peritonitis once established and allowed to run its natural course is, except in rare instances, fatal. Moreover, the only method of treatment which gives any practical chance of recovery is operative or surgical. The surgeon, having once satisfied himself that the patient is suffering from acute general peritonitis, has only to decide one point—whether the patient is in a condition to withstand operative interference. To do this he has to consider first of all whether a thorough attempt can be made under a general anæsthetic; in this event, laparotomy, flushing, and drainage of the peritoneal cavity must be promptly carried out. But if he think that the patient cannot stand this ordeal it may be possible to anæsthetise the patient for a short time so that an abdominal section can be rapidly performed and a drainage-tube and gauze introduced. In extreme cases a general anæsthetic may be quite out of the question, and the surgeon must then attempt to do what is necessary with a local anæsthetic. In the experience of the writer, patients who are extremely ill with peritonitis can withstand a rapidly performed abdominal section with local anaesthesia better than might be expected. The details of these operative procedures are as follows:—

1. *Laparotomy, flushing, and drainage.*—The patient being under the influence of ether or chloroform, a free incision is made in the middle line below the umbilicus. There is a considerable diversity of opinion among surgeons concerning the best anæsthetic for abdominal work. From the surgeon's point of view alone it seems to the writer that chloroform is the best both for the rapid and comfortable performance of the operation, and for the absence of the pulmonary disturbances so common after ether. From the anæsthetist's point of view, which is concerned solely with the patient's safety during the actual operation, the consensus of opinion in London is strongly in favour of ether (p. 61). With a competent 'chloroformist' the writer considers, however, that the safety of the patient during the operation and the few succeeding days is greater with chloroform than with ether. A rapid search is made for the seat of origin of the trouble. If the appendix is the offending organ, an incision should be made at a spot over it most convenient for its removal, and, if possible, the appendix is excised. All signs of local suppuration should be washed and sponged away. The part of the abdomen in the region of the appendix, especially the cavity of the pelvis, should be well flushed out with normal saline solution at the temperature of the body. An indiarubber drainage-tube is placed in contact with the spot where the disease originated, whether appendix, Fallopian tubes, or elsewhere, and around this tube some iodoform-gauze should be packed. The median wound should then be

closed, and one or two stitches placed in the lateral incision so as to prevent prolapse of intestine, and at the same time not to interfere with effective drainage. If no local focus can be found, the abdominal wound may be closed after thoroughly flushing the peritoneal cavity.

Some details concerning the *technique of drainage* must be borne in mind. If a tube be inserted, say, six inches from the skin down towards the pelvis, and carefully examined at an autopsy twenty-four hours afterwards, it will be seen that the tube is surrounded by coils of intestine which are sealed together with exudation which completely prevents the tube receiving any appreciable amount of the general peritoneal fluid. The surface of the coils surrounding the tube exudes the turbid serum which fills the test-tube-like cavity. As soon as this liquid is removed by a syringe or by gauze the coils gradually exude another quantity. Unless the tube reaches directly down to a septic focus it seems to be of little use in draining the general peritoneal cavity. By leading down to a septic focus it helps to form a well-protected channel for the exit of any discharge from the suppurating focus. Drainage-tubes, whether made of glass or indiarubber, are quite useless as agents for draining the general cavity of the peritoneum, even when present in numbers; and indeed may do harm by mechanically irritating the coils of intestine. The sole use for a drainage-tube is to obtain a channel through the coils of intestine by which some septic focus can discharge its contents to the exterior with ease. There is one exception to this rule, and that is in the case of the pelvis. Here there is naturally a tendency for fluid to collect in a definite quantity, so that a tube reaching to the bottom of the pelvis must assist in draining that cavity. So important is the draining of the pelvis that some surgeons prefer to drain Douglas's pouch in women by an opening through the vagina. This proceeding, however, necessitates additional shock, which is an important factor in cases of acute peritonitis, and its necessity is doubtful if efficient drainage is secured by a tube and gauze from above.

One of the most disappointing features in the surgical treatment of general peritonitis is that after removing the focus or origin of the trouble and thoroughly flushing the abdomen, without markedly depressing the patient, there is a tendency to distension of the intestine, especially the small gut. The reasons for this distension have been already given, and it is chiefly to the late Greig Smith that we are indebted for pointing out how very important it is to drain the inside of the alimentary tube as well as the peritoneal cavity. If the intestines are much distended one of the most distended coils should be incised, and a T-shaped glass tube inserted. In these desperate cases the first point is to save the patient's life; in the event of recovery the artificial anus can be easily closed by modern methods.

2. *Rapid laparotomy with drainage.*—The patient is quickly anaesthetised, and as soon as the abdominal wall is flaccid a median incision is made and any inflammatory exudation is allowed to escape; if rapid examination reveals the focus of origin a tube and gauze-drain are inserted down to the suppurating spot. If the seat of origin cannot be found a gauze-drain may be left in the peritoneal cavity and the wound partially closed. If the intestine is much dilated the first distended coil should

be opened, and a T-shaped glass tube inserted as described above.

3. *Laparotomy with local anaesthesia.*—If the patient is too bad for the administration of a general anaesthetic, the skin of the abdomen in the middle line should be rendered anaesthetic with *β*-eucaine (see ANÆSTHESIA, LOCAL). As much should be done as the patient can bear under the conditions of local anaesthesia.

In no department of surgery is it more important for the surgeon to form his opinion with decision, to commence operation without delay, and to operate quickly. Nothing is more certain than that every additional minute of exposure in the case of an abdominal section diminishes the patient's chances of recovery.

After-treatment.—(1) If the patient is restless after the operation, a hypodermic injection of morphine (gr. $\frac{1}{4}$) and atropine (gr. $\frac{1}{150}$) should be given. (2) It is so important to keep the alimentary canal at rest that the introduction of food into the stomach should be prohibited. All food should be given by the rectum; perhaps the best is peptonised beef-tea and small quantities of brandy. This is quite sufficient to tide the patient over the crisis of the disease. As a rule, if a patient is alive on the fourth day after operation he will recover. (3) Thirst is best satisfied by injections of warm water *per rectum*. If the patient craves for something by the mouth, a little warm water, or, if much preferred, a little iced-water may be given. In cases of excessive thirst a feeder full of water (5 oz.) may be given. If this is vomited no great harm is done, providing it is not frequently repeated. (4) After the operation no aperient should be given for the first twenty-four hours. As soon as the patient has rallied sufficiently from the operation, and if there is distension of the intestine, an enema of water (a pint) combined with tincture of valerian (a drachm) should be given. If at the end of twenty-four hours the patient is improving, small doses of sulphate of magnesium and sodium may be given, say \mathfrak{zj} of each every three hours, or small doses of calomel (gr. $\frac{1}{2}$) every three hours.

The administration of opium and morphine.—Before the question of operative treatment has been discussed no opium or morphine in any form should be given. The administration of this drug causes an immediate improvement in the symptoms: the pain is diminished, the rigidity of the abdominal muscles may disappear altogether, and the patient's general condition is so much improved that the surgeon may be quite deceived as to the gravity of the case. Many lives have been lost owing to the false appearance of improvement brought about by the administration of this drug (p. 780). The patient's improvement may be maintained until suddenly the dose of poison absorbed from the peritoneal surface reaches its maximum, and the patient suddenly collapses. If the case is considered too bad for operative interference then morphine may be given until the patient is quite relieved of all distressing symptoms. Morphine again may be very useful in stimulating the heart and quieting the nervous system after an operation has been performed. In these cases, however, it should be given with especial care that no inertia of the intestines is produced.

A method of treatment which has gained considerable ground on the Continent, especially in France, is the subcutaneous and intra-venous injection of

saline solution. The principle is to introduce into the vascular system, directly by the veins or indirectly by the subcutaneous lymphatics, a saline solution with a view of washing out the lymphatic vessels and blood-vessels, and so enabling the liver and kidneys to get rid of the toxins. The solution generally used is sodium chloride 5 grms., sodium sulphate 10 grms., distilled water 1 litre. This is injected at the temperature of the body either in the subcutaneous tissue or through the median basilic vein (*see* SALINE SOLUTION, Infusion of). According to French surgeons remarkable improvement and cures have been attained. This treatment seems perfectly rational when used in conjunction with operative interference as recommended by some French surgeons. It is really very similar to the 'infusion' that we often perform upon such patients who are collapsed after the operation. The amount of fluid injected averages about 5 litres in the course of twenty-four hours.

Non-operative treatment.—According to our present knowledge there is no method of attempting to cure a case of acute general peritonitis by medicinal means. In cases too much collapsed for surgical interference the treatment must be directed to the alleviation of all distressing symptoms.

HENRY PERCY DEAN.

PERITONITIS, Acute Localised.—Acute inflammation of a portion of the peritoneum due to some lesion of the organ which it is covering is of very common occurrence. It may occur in the peritoneum covering the liver and spread thence to the peritoneum lining the lower surface of the diaphragm. It not infrequently occurs in the peritoneum covering the stomach in the neighbourhood of a gastric ulcer. Of all the abdominal organs the vermiform appendix is the one most commonly affected. In women there is frequently local peritonitis around the uterus and Fallopian tubes, usually termed 'pelvic peritonitis.' The chief varieties we will consider at greater length.

1. Sub-phrenic Abscess.—Inflammatory conditions may spread from the pleural cavities through the diaphragm to the abdomen. As a rule, however, sub-phrenic peritonitis spreads from the abdominal organs, chiefly the liver and stomach, often developing into an abscess. When the inflammation spreads from the liver and suppuration occurs, the abscess forms beneath the right half of the diaphragm, and is very often diagnosed as an empyema. On the other hand a sub-phrenic abscess caused by lesions of the stomach forms on the left side.

The symptoms and diagnosis of sub-phrenic abscess are considered in the article on STOMACH, Perforation of, and its Results.

TREATMENT.—As soon as pus is suspected in the region of the diaphragm an exploring needle should be used (*see* PARACENTESIS). If the result is positive some indication is obtained as to the situation of the pus and its depth from the surface. If the needle gives a negative result the surgeon must proceed to make a careful dissection down to the diaphragm in the region of its attachment to the ribs. Very often the pleural cavity overlaps the displaced diaphragm to the extent of several inches. In such cases, if the condition of the patient will allow, the lower end of the parietal pleura may be stitched to the chest-wall, and the wound plugged with iodoform-gauze for 24 or 36 hours until adhesion

has formed to a sufficient extent to allow the surgeon to cut straight through the diaphragm. If after removing a piece of rib it is seen that the pleural cavity is normal the surgeon should extend his dissection in a downward direction, until the point of reflection of the pleura is seen. The pleura may then be pushed up, and gauze packed tightly in the upper part of the wound. If immediate evacuation of pus is necessary the diaphragm may be incised, the pus quickly removed, and the edges of the incised diaphragm stitched to the edges of the wound. The risk of infecting the pleural cavity is by no means a light one: it is not due so much to the pus escaping into the pleural cavity at the time of the operation as to the soaking of pus into the surrounding tissues within the few hours succeeding the operation, especially if drainage from the abscess cavity is not quite free or if the upper part of the wound, in the region of the pleura, is not carefully and thoroughly packed with iodoform-gauze. There is one consolation for the surgeon, viz. secondary infection of the pleura is common in sub-phrenic abscess, even before operation, so that if the germs have reached the pleura before the surgeon, nothing the latter can do is likely to prevent the development of an empyema. The following rules may be worth remembering in dealing with the surgery of sub-phrenic abscess: (1) To make the incision over the spot where pus has been found by the needle; (2) if no pus has been obtained by the needle to make a careful exploratory operation through a four-inch incision over the tenth rib in the mid-axillary line; (3) if no great urgency, to pack the exposed pleura or pleural cavity with sterilised gauze and wait 24 to 36 hours before incising the diaphragm; (4) if evacuation of the pus is urgent, to try and expose the lower reflection of pleura, push it upwards from the ribs and pack tightly with gauze, incise the diaphragm and stitch it to the skin, insuring free drainage.

2. Abscess around Appendix.—Owing to the inconstant position of the appendix the situation of the abscess is, as a consequence, variable. Usually it is in the right iliac fossa with the cæcum on its outer side. Sometimes it is wholly within the pelvis. It may be to the left side of the median line, in the iliac region. An important situation is *sub-mesenteric*; the abscess being limited above by the oblique line of the mesenteric attachment, viz. from the right sacro-iliac synchondrosis to the left side of the second lumbar vertebra—below it reaches the hollow of the sacrum, being variably limited by coils of the small gut; to the right side is the cæcum; in front the mesentery itself and numerous coils of gut form the boundary, so that the general peritoneal cavity is exposed after cutting through the abdominal wall.

TREATMENT.—When there is a dull area in the iliac fossa the incision should be made over the spot of maximum intensity. The cutting should be done carefully so that any weak adhesions may be left in order to keep the pus from spreading. In all cases the whole of the pus should be removed at once and the cavity thoroughly washed out. If the appendix can be easily got at, it should be excised; as a rule, however, it forms a part of the abscess-wall and cannot be felt or seen. There is often a faecal concretion present which usually escapes through the gangrenous aperture in the appendix, and it is important to try and get hold of this;

this may often be attained by the gentle use of a blunt Volkmann's spoon. If the whole of the pus is evacuated, a large drainage-tube inserted and surrounded with iodoform-gauze, the cases usually do well without any infection of the general peritoneal cavity. When the pus is chiefly in the pelvis and can be felt *per rectum*, a good plan is to reach the abscess *via* the right ischio-rectal fossa. The skin is incised midway between the margin of the anus and the ischial tuberosity, and the tissues of the fossa are incised until the levator ani is reached. This may be penetrated with a pair of sinus-forceps, and the opening dilated to allow the passage of a large drainage-tube. The writer has found this plan very successful in a case in which the pus was high up and gave no indication of its proximity by any alteration in the tissue of the ischio-rectal fossa. See also APPENDIX VERMIFORMIS, Inflammation of, p. 93.

3. **Pelvic Peritonitis and Abscess.**—This may start in the uterus or Fallopian tubes, usually after parturition. The tubes are most often the infecting focus. These abscesses are often opened *per vaginam*. See p. 1200.

HENRY PERCY DEAN.

PERITONEUM, Chronic Inflammation of.
SYNON. : Chronic Peritonitis.—This affection, like the acute form, may involve the peritoneum more or less generally; or only over a localised and limited area. The conditions included under the term are somewhat indefinite, but not uncommonly they are well marked pathologically, as well as of considerable clinical importance.

ÆTIOLOGY AND PATHOLOGY.—Without entering into details, it must suffice to point out the circumstances under which chronic peritonitis may occur: (1) There is no doubt as to its being, though rarely, a sequel of one or more attacks of acute or subacute peritonitis, either general or local, but especially the latter; and after a circumscribed acute peritonitis chronic changes may gradually spread more or less widely. Moreover, the conditions remaining after an attack of peritonitis are liable to set up further mischief of a chronic nature. (2) Chronic peritonitis may become associated with ascites, but more particularly when repeated paracentesis has been performed for the relief or cure of this condition. In some of these cases probably the ascites is the result of a simple chronic peritonitis. (3) Localised chronic peritonitis is common as the result of continued irritation, associated with some diseased organ, such as a cirrhotic or cancerous liver, cancer or chronic ulcer of the stomach, old hernie, tumours, and various other obvious conditions. There are, however, cases occasionally observed in which the cause is not so evident, and these have been attributed to irritation by accumulation of fæces, or to repeated pressure or other mechanical causes acting from without. Extensive chronic peritonitis also starts occasionally from a local centre, especially perihepatitis. (4) Morbid processes in the peritoneum itself are very liable to set up chronic inflammation. Of these the principal are tuberculosis and cancer; and tubercular and cancerous peritonitis constitute important forms of this disease. (5) In rare instances a chronic inflammatory effusion collects in the peritoneal cavity without any obvious cause. The fluid is generally serous, and cannot be distinguished from that of ascites. This chronic effusion has been noticed

during convalescence from fevers. Distinct chronic peritonitis also sometimes occurs as an independent disease, and has then been referred to chronic Bright's disease, alcoholism, gout, rheumatism, lead-poisoning, cardiac disease, and other causes.

ANATOMICAL CHARACTERS.—Adhesions or fibrous thickenings connected with the serous membrane are almost constantly present in different degrees, and not infrequently they constitute the sole anatomical evidences of chronic peritonitis. They result from the development of the inflammatory products, and the formation of connective or fibrous tissue, with new vessels. The thickening varies much in degree, ranging from what is scarcely perceptible, to the production of a dense fibrous mass an inch or more in thickness, as the writer has seen. It may be evident in the parietal peritoneum; around organs, forming more or less thick and firm capsules; or in the peritoneal folds, especially the omentum and mesentery. Adhesions or agglutinations also form between different parts, thus uniting organs to each other, to the abdominal walls, or to the mesentery or omentum; or sometimes matting the whole together into an inseparable and indistinguishable mass. They present great variety, and by the movements which take place within the abdomen adhesions may be stretched or made looser, or even be got rid of altogether in some instances, when they have formed after an acute attack. On the other hand, in many cases the adhesions and thickenings tend to become gradually stronger and denser, and at the same time to undergo contraction, so that they produce serious effects.

In many cases of chronic peritonitis effusion of some kind is observed. It may be merely a clear straw-coloured serum, or with fibrinous flakes, sero-purulent, or actually purulent. Blood may also be present in it. Occasionally this is the prominent or only anatomical change; and the fluid may range in quantity from a small to an enormous amount. Usually it is associated with the other conditions already described, so that the fluid is not free to move about, and may be actually circumscribed, or even lie in the substance of fibrous masses. Purulent accumulations are likely to make their way in various directions, either outwards or into internal viscera.

When chronic peritonitis is associated with tuberculosis, cancer, or other morbid formations, these will be evident on *post-mortem* examination. Moreover, as the result of degenerative processes, caseous or cretaceous particles or masses may be found. Pigment is also often present in abundance. The peritoneal veins may be extensively dilated and varicose.

It is important to notice the obvious effects liable to be produced upon the abdominal organs and other structures by chronic peritonitis. They are more or less fixed by the adhesions and thickenings, and may be displaced at the same time. Compression or constriction is often produced, especially important in the case of hollow viscera, as well as distortion, twisting or torsion, and incarceration. Some of these effects may occur suddenly or acutely in connection with bands of adhesion, thus giving rise to grave consequences; and fixation of the bowel may also lead to intussusception. The omentum may be greatly distorted, or contracted and gathered up in some abnormal situation; while the mesentery has been found extremely shortened so

as to contract the small intestine to half its length, its serous covering and longitudinal muscular layer being shrivelled, and its mucous lining thrown into transverse folds. It is said, however, that the small intestines are usually not compressed, or even adherent among themselves, though they are contracted in diameter. The deeper tissues of some of the abdominal viscera are likely to be affected by long-continued chronic peritonitis; and atrophy from compression may ensue. The muscular coat of the bowel is generally wasted, but that of the stomach is sometimes much thickened. As one good result of local chronic peritonitis, mention must be made of the fact that it is not uncommonly the means of preventing or modifying the injurious consequences resulting from some forms of perforation of abdominal viscera, by giving rise to previous adhesions and thickenings, and thus obviating the escape of their contents, or limiting their dissemination.

SYMPTOMS.—According to its mode of origin, chronic peritonitis either remains after an acute illness, or after a succession of more or less acute or subacute attacks; or its onset is gradual and chronic from the first, and may be very insidious. Of slight adhesions left after acute peritonitis, or originating from chronic causes, there are often no clinical signs; or there may be uneasiness and discomfort, or even painful sensations at times in some part of the abdomen, especially the iliac region, with a tendency to intestinal disorder, in the way of spasmodic movements and constipation. Even when there are no symptoms whatever, adhesions may at any time cause serious consequences. In well-marked cases of chronic peritonitis the symptoms to be expected are of the following nature: Abnormal subjective sensations are usually experienced in the abdomen, such as tightness, fulness, dragging, or actual pain. The pain, when present, is of a dull character, not severe, and liable to come and go, or to present exacerbations from time to time; it is often localised, and especially if the peritonitis be circumscribed; sometimes there is a feeling of local soreness or heat. The painful sensations tend to be increased by movement, and by shaking the body. They are sometimes aggravated by posture, in some cases by bending forwards, in others by the erect posture; and they may be increased by going up stairs, especially if the abdomen is distended. More or less tenderness on pressure is very common, even when there is no spontaneous pain, but not invariable; it is frequently more evident at certain spots, where it may be considerable. Colicky pains are not unusual in chronic peritonitis, and may occur in severe paroxysms, especially after food, being due to the disturbed action of the bowels, associated with the production and movements of flatus, which may be abundant, even amounting to tympanites. Appetite is often impaired or variable; and dyspeptic symptoms are frequent. Constipation is the rule, and may be very obstinate, even amounting to obstruction under certain conditions. Sometimes diarrhoea is present, or it may supervene at intervals, and occasionally it assumes a dysenteric character. This symptom is most likely to be met with in tubercular peritonitis. In some cases vomiting occurs from time to time. When there is considerable effusion in the peritoneum, the secretion of urine is diminished. Respiration may be mechanically interfered with from the same cause. As the result of pressure by

fibrous thickenings and other conditions upon different structures, jaundice, ascites, oedema of the legs, thrombosis, albuminuria, or neuralgic pains may supervene. When the organs are all matted together, their entire functions must necessarily be more or less interfered with.

General symptoms are usually present in various degrees in cases of chronic peritonitis, but in many instances they depend mainly upon the condition with which this disease is associated, especially tuberculosis and cancer. These symptoms include pyrexia, not high, and having no regular course, but presenting exacerbations, either persistent or occurring at intervals, and in some cases assuming a hectic character; increased frequency of the pulse; a sense of languor or weakness; and more or less general wasting and anæmia, with dryness and harshness of the skin.

It must be noted that in some cases of chronic peritonitis, even where there is considerable effusion, the local and general symptoms are very slight and indefinite, and the patient only suffers from the discomfort due to the accumulation of fluid. On the other hand, the progress is not uncommonly from bad to worse, ending in extreme emaciation and exhaustion, with the formation of bed-sores; or there may be a succession of improvements and relapses; while various phenomena result from the opening of collections of pus in different directions. Thus death may gradually or rapidly terminate a case; or pyæmia may supervene. Even in bad cases, however, comparative recovery may ensue, only the effects of the inflammation remaining, and being more or less troublesome.

PHYSICAL SIGNS.—These may be the only clinical indications of chronic peritonitis. They necessarily differ in detail according to the nature of the abnormal physical conditions present in the abdomen, and are also liable to alter during the progress of a case; but their general characters are sufficiently definite. (1) In general chronic peritonitis enlargement of the abdomen is observed, mainly in proportion to the amount of fluid present; but it depends partly on gas in the intestines, or in certain cases on extensive fibrous thickening. As a rule, it is not very considerable; but the abdomen may attain an enormous size, with stretching of the skin and other accompanying phenomena. While regular in shape on the whole, it may present more or less want of symmetry, especially after a time. On the other hand, in some instances the abdomen becomes locally or generally retracted, and may then exhibit marked irregularities. (2) The sensations on palpation are very variable, but often highly characteristic. It may happen that there is a uniform feeling of fluid, or of more or less firm resistance. More commonly the sensations are not uniform, but differ in different parts of the abdomen, including indistinct fluctuation in localised areas, sometimes very limited and in unusual situations; with firmness or resistance around these areas or in other parts, ill-defined, occasionally nodulated; and even distinct tumours may be felt, more or less irregular. These in some instances are due to morbid growths, such as cancer, but they may also originate in organised inflammatory products. Under certain conditions the abdomen yields a peculiar feeling of being movable as a whole. Abnormal movements of the bowels are sometimes recognised. When there are localised

adhesions between the visceral and parietal peritoneum, if pressure is made at a little distance from the seat of an adhesion, the skin will rise in a fold where this adhesion exists. Possibly general adhesions might be made out by palpation. (3) Percussion occasionally reveals freely movable fluid. As a rule, however, it shows that the fluid is not freely movable, or that it is actually loculated irregularly, this condition being associated with more or less solid material. Hence there is extensive and diffused dullness, which may be noticed mainly in front, and not in dependent parts. Not uncommonly patches of dullness and tympanitic resonance are found contiguous to each other, and irregularly distributed, unaffected by posture. Over the fluid fluctuation may, perhaps, be elicited, but indistinctly; and where there is much solid, the sensation on percussion is that of undue resistance. (4) Friction-fremitus and friction-sound are sometimes present. (5) Changes of posture, as a rule, produce comparatively little or no effect upon the shape of the abdomen, the sensations on palpation, or the percussion-sounds.

When chronic peritonitis is localised, it may be practicable to detect the condition by palpation and percussion. Moreover, when certain organs become fixed by peritoneal adhesions, especially if they are diseased at the same time, this state of things may often be recognised by noticing that the affected organ does not present its normal mobility.

DIAGNOSIS.—In most instances chronic peritonitis, if of any extent, can be recognised without much difficulty, by attending to the history of the case, the symptoms, and the physical signs. It may be very difficult, or even impracticable, to distinguish positively between mere ascites and chronic inflammatory effusion. All the circumstances of the case must be taken into consideration; and in doubtful cases the removal of some of the fluid, by means of a small trocar, will aid the diagnosis. It is important to determine the cause of chronic peritonitis, when present, and especially whether it is simple, tubercular, or malignant. Here, again, the whole case must be considered, not forgetting the age of the patient, the family history, and the presence or absence of tubercle or cancer in other parts. It has been said that a hæmorrhagic character of any fluid removed is significant of tubercular or malignant peritonitis, but this certainly cannot be relied upon.

It is quite impossible to diagnose with certainty obscure cases of localised chronic peritonitis, though the condition might be suspected; and it may become very difficult, even in pronounced cases, to determine the precise changes within the abdomen.

PROGNOSIS.—The prognosis of each case of chronic peritonitis must be considered on its own merits, as regards the cause of the disease; its extent and products; the progress of the morbid changes; the effects produced on the abdominal structures; and the general symptoms. Some cases are of little or no consequence; others are very serious; but even in apparently severe cases great improvement, or even practical recovery, may take place. The dangers to be feared from the opening of purulent collections in various directions must be borne in mind; and also those liable to arise from the presence of bands of adhesion within the abdominal cavity. Tubercular and carcinomatous peritonitis are necessarily very grave forms of the

disease, but the former may certainly be recovered from.

TREATMENT.—With regard to the *local* conditions in chronic peritonitis, it is often desirable to endeavour to promote the removal of morbid products within the abdomen. For this purpose it may be important to keep the patient entirely at rest in bed for a time. The internal administration of iodide of potassium or syrup of iodide of iron may be tried; and in some instances diuretics might be of use. Possibly the judicious administration of some mercurial preparation would be serviceable in appropriate cases. Violent purgation is to be deprecated; but where there is much fluid, advantage might be derived from repeated diaphoresis, induced by means of the hot-air, vapour-, or Turkish bath, or by the use of jaborandi or pilocarpine. Local measures are in some instances of essential service, namely, counter-irritation, especially by the application of iodine; friction with some oil or ointment; the application of mercurial ointment or liniment on flannel; and pressure. The writer has found pressure decidedly valuable in aiding absorption in certain cases, as well as in giving support, the abdomen being covered with cotton-wool, and a suitable bandage applied more or less firmly. A flannel bandage answers best. In cases of large effusion, where absorption cannot be effected, the writer has no hesitation in recommending paracentesis, even repeated when required, having seen signal benefit follow this treatment. A localised purulent accumulation must be treated on ordinary surgical principles. *See also* PERITONEUM, Tuberculosis of.

General treatment is often of essential value in cases of chronic peritonitis. It is directed to the condition upon which the disease depends, such as tuberculosis, or to its effects, but the measures are similar in the main, consisting of good nutritious diet, suitable sanitary conditions, change of air, and the administration of cod-liver oil, quinine, preparations of iron, and other tonics and nutrients. Wine may often be given with advantage.

Symptoms will probably need attention from time to time, such as pain, flatulence, dyspeptic disorders, constipation, diarrhoea, and various other disturbances. The organs in general must be looked to, and their functions promoted. A free flow of urine often follows absorption of fluid, or its removal by operation.

FREDERICK T. ROBERTS.

PERITONEUM, Dropsy of.—*See* ASCITES.

PERITONEUM, Hæmorrhage into.—Blood may escape in quantity into the peritoneal cavity as the result of external injury; or from the rupture or perforation of different structures within the abdomen. An important form of hæmorrhage is that which results from the rupture of an aneurysm. More or less blood may be present in inflammatory or dropsical effusion; or it may originate in the opening of vessels by morbid growths, or the spontaneous rupture of new vessels. Peritoneal hæmorrhage is not uncommon in connection with tubercular and malignant peritonitis. It may also occur from scurvy or purpura. Fatal hæmorrhage has taken place into the peritoneum owing to the rupture of enlarged veins, due to portal obstruction.

SYMPTOMS.—It might possibly happen that peritoneal hæmorrhage could be recognised during life,

if there were some evident cause for this condition ; followed by the physical signs of the presence of the blood in the peritoneal cavity ; and general indications of loss of blood. As a rule, however, the condition cannot be detected clinically. The hæmorrhagic nature of an effusion can only be recognised by withdrawing a portion of it.

TREATMENT.—This merely consists in the local and general treatment for loss of blood, unless any thing can be done surgically.

FREDERICK T. ROBERTS.

PERITONEUM, Malformations of.—It will suffice to mention under this head that the folds of the peritoneum, such as the mesentery, may be abnormal in length or formation ; that unusual bands or openings may be present ; and that prolongations of the peritoneum, which naturally become obliterated or shut out from the general cavity, sometimes do not undergo these changes, as may be illustrated by the occasional patency of the process of the serous membrane which descends with the testis into the scrotum. As the result of these abnormalities, displacements of organs may occur ; or their movements may be restricted or too free ; or constriction of the intestine may take place. These conditions can only be recognised clinically by their effects ; and not uncommonly they cannot be made out in any way. Treatment may sometimes be directed to their cure, as is exemplified in the radical cure of a congenital hernia.

FREDERICK T. ROBERTS.

PERITONEUM, Morbid Growths of.—Malignant growths are comparatively rare in the peritoneum. They are most commonly secondary, originating from extension, or as a distinct secondary formation ; and chiefly following malignant disease of the alimentary canal, especially the stomach, liver, pancreas, retro-peritoneal glands, and female generative organs, particularly the ovary. Malignant growths are very rare under thirty, but have been observed even in childhood. Most cases occur between fifty and sixty. The disease is much more common in females than in males.

Peritoneal cancer is generally of the scirrhus type, but is occasionally encephaloid, melanotic, or colloid, the last being comparatively frequently found here, and it may form an enormous mass. Primary growths, though differing little in structure, are classed as *endotheliomata* (see TUMOURS). Usually chronic, it either takes the form of separate nodules, which are often umbilicated ; or of an infiltration, sometimes of great thickness. Probably this appearance is due to an aggregation of nodules. Each nodule may send out processes, which tend to pucker and drag the neighbouring part of the peritoneum to it as a centre. The distribution of the nodules is very variable. They are usually far more abundant in the flanks and over the diaphragm than elsewhere. The omentum may be drawn up into a solid mass, as in tubercular disease. Generally there are associated signs of chronic peritonitis, with more or less effusion, which is often hæmorrhagic ; extensive hæmorrhages sometimes take place. Abdominal organs are usually found implicated ; or the cancerous process may lead to their destruction or perforation. In some instances there is a large dropsical effusion in the peritoneal cavity.

SYMPTOMS AND DIAGNOSIS.—The clinical phenomena in different cases of peritoneal cancer are

very variable in their exact nature, but their general characters may be readily understood. At first the disease will probably be obscure, and the symptoms indefinite. Abdominal pain is commonly complained of, and is often increased paroxysmally from intestinal disorder ; tenderness here and there is also generally marked. There may be signs of more or less disturbance of abdominal organs, or one or other of these is in most instances also the seat of disease. Cancerous growths in the peritoneum tend to interfere considerably with the alimentary canal, and by their contraction and puckering may cause marked narrowing of the intestinal tract, or even give rise to ileus. They may produce other symptoms by pressure on various structures. Ascites is a very frequent symptom ; and jaundice sometimes occurs. Physical examination will reveal signs of the growth itself ; of chronic peritonitis ; and of ascites. Cancerous nodules may originate friction-sounds. In some instances a hard thickening or mass is evident in the tissues around the umbilicus, which may also look red and inflamed. If fluid is withdrawn from the peritoneal cavity, it is usually more or less mixed with blood ; and marked anaemia or fainting may result from hæmorrhage. The general symptoms and cachexia of cancer become pronounced during the progress of the disease. Its course is occasionally somewhat acute, with pyrexia ; as a rule, it is more or less chronic, with little or no fever, or this only occurs at intervals. The termination is necessarily invariably fatal.

It is necessary to offer a few separate remarks about *colloid* involving the peritoneum. This condition is attributed to a colloid degeneration of a carcinoma. All the abdominal viscera may be enveloped in thick layers, consisting of round gelatinous masses. Many of these are attached only by the most delicate threads, or even seem to be free. It is a very rare disease, but when present in a marked form is, according to the writer's limited experience, easily recognised clinically by the following physical signs : (1) The abdomen is greatly and may be enormously enlarged, but is not quite uniform or symmetrical ; the umbilicus is only stretched, not everted. (2) Palpation generally reveals a feeling of diffused resistance, with rather firm, irregular masses. Fluctuation is either absent or very indistinct. (3) There is extensive dullness, with resistance, over the abdomen, the anterior regions being markedly dull, and there being no indications of accumulation of fluid specially in the flanks. (4) Usually a change of posture produces little or no effect upon the physical signs. (5) A slimy gelatinous fluid may possibly be removed by the exploratory needle or aspirator ; and occasionally a similar fluid is said to be discharged *per rectum*, or from the stomach.

TREATMENT.—Nothing can be done in cases of malignant disease of the peritoneum, except to treat symptoms.

Rare formations.—Among rare formations found in the peritoneum may be mentioned hydatids, associated or not with a similar disease in one or more organs ; serous, dermoid, and colloid cysts ; fibromata ; myxomata ; and remains of blood-clots. The peritoneum may be involved in actinomycosis.

FREDERICK T. ROBERTS.

PERITONEUM, Tuberculosis of.—Tuberculosis of the peritoneum occurs (1) As a part of general

acute tuberculosis; (2) As a localised formation, in connection with tubercular ulcers in the intestines, granulations forming on the corresponding surface of the peritoneum; (3) As a definite local disease, usually assuming a more or less chronic or subacute course, and accompanied by peritonitic changes. The last form is a well-recognised disease of early life, and is then usually a part of the condition termed *tabes mesenterica*, being associated with tubercular ulceration of the intestines, and tuberculosis of the mesenteric glands (*see* p. 1002). Most cases occur under thirty years of age, but the complaint may be met with over fifty. It appears to be much more frequent in males than in females. In the latter it is in the large majority of fatal cases found to be accompanied by tubercular disease of the Fallopian tubes, which is probably set up by extension from the serous surface. In men the epididymis or testis is sometimes affected on one or both sides. The pleure are not uncommonly involved, and occasionally the pericardium. Pulmonary tuberculosis is usually present, to which the peritoneal mischief may be secondary, but this is not always so pronounced as to be diagnosed during life, at any rate without careful examination. Tubercular ulceration of the intestines is frequently associated with the peritoneal lesion.

ANATOMICAL CHARACTERS.—The morbid conditions found on *post-mortem* examination in pronounced cases of tubercular disease of the peritoneum consists of a combination of disseminated tubercles in different stages, with signs of peritonitis. The peritonitis is generally chronic (*see* p. 1201), but may be acute. The tubercles are not uniformly scattered, and are said to be especially numerous on the under surface of the diaphragm and in the flanks, while the surface of the intestines may be comparatively free. They have usually undergone more or less caseation or fibrous change in different parts. As the result of the peritonitis, great thickening and extensive adhesions are usually present, with much contraction. The omentum is in many cases drawn up into a firm flattened mass across the upper part of the abdomen, below the stomach, and often contains much caseous matter, or recent tubercle. The mesentery is also contracted, drawing the intestines together, and distorting them. The bowels may be completely matted together, and perforated by tubercular ulcers at different points. More or less effusion is almost always present, consisting of turbid serum or pus; and it often contains altered blood in variable quantity. Sometimes abundant hæmorrhage takes place into the peritoneum. The effusion is frequently localised by adhesions at different points; or it may be ultimately removed altogether, only adhesions being left.

SYMPTOMS.—The clinical phenomena present considerable variety in different cases, as regards their nature and progress (*see* p. 1201). In some instances tubercular disease of the peritoneum begins acutely, or in a succession of acute attacks, usually circumscribed, with symptoms like those of peritonitis, then subsiding into a chronic condition. Far more commonly the progress is subacute or chronic and insidious, or even latent for a time. In other cases there are marked remissions of the symptoms during their progress, both local and general. The phenomena may be summarised as those of the peritoneal inflammation already described, and the presence of firm lumps in the abdomen, mainly revealed by physical examination; with general sym-

ptoms of tuberculosis, usually in a pronounced degree; and often signs of implication of other important organs and structures in the tubercular mischief. In exceptional instances in the writer's experience the prominent condition has been abundant effusion of fluid in the peritoneal cavity, usually recurring after repeated removal, but in one case ultimately completely cured. The detection of the great omentum, which is felt as a rounded mass, extending more or less obliquely across the upper part of the abdomen, is highly significant in the diagnosis of tubercular disease of the peritoneum. In some cases there is firm thickening, with redness and soreness, around the umbilicus, which is usually due to extension of inflammation from the peritoneum along the obliterated umbilical vessels to the surface. Occasionally the umbilicus has given way, and a discharge of pus has taken place from the peritoneal cavity. Tubercular peritonitis is usually chronic in its progress. It is a serious disease, but is not so fatal as was formerly supposed, especially in young subjects, and when treated in accordance with modern views.

TREATMENT.—The general measures suitable for tubercular disease must be carried out, as well as those already indicated for chronic peritonitis, as above stated. Wilks recommends the administration of iodide of potassium, with or without quinine, and inunction over the abdomen with liniment of mercury, followed by the application of tincture of iodine. The writer has seen remarkable benefit follow the administration of guaiacol carbonate in cases of undoubted tubercular peritonitis, and in one instance a complete cure was effected.

OPERATIVE TREATMENT.—Of late years the principle of opening and draining the peritoneal cavity has been extensively advocated. This treatment is especially recommended in cases in which there is extensive accumulation of fluid either free in the peritoneal cavity or confined to special parts by adhesions. The dry caseating forms with extensive adhesions are less amenable to operative interference, which indeed is itself less practicable. The abdomen is usually opened, with strict antiseptic precautions, in the middle line below the umbilicus. All the fluid is allowed to escape and the cavity carefully dried with 'swabs.' Any diseased omentum that can without difficulty be removed is excised, and, in women, the Fallopian tubes, if tuberculous, should also be removed. When localised collections of fluid are found, the whole peritoneal cavity may be flushed with boric-acid solution or sterilised saline solution. This treatment with the general disturbance of the intestines which it involves is often followed by great benefit. The mortality varies from 3 to 8 per cent., and the cures are said to exceed 60 per cent. These figures, of course, only refer to operations upon carefully selected cases.

FREDERICK T. ROBERTS.

PERITYPHLITIS (περί, around; and τυφλόν, the cæcum).—*See* APPENDIX VERMIFORMIS, Inflammation of.

PERI-UTERINE HÆMATOCELE.—*See* PELVIC HÆMATOCELE.

PERSONAL HEALTH.—Personal hygiene is the science of individual health. As there are public acts and laws which, observed, promote the health of communities, so there are rules of living

and habits of life, by attention to which the health of the individual may be preserved or increased. Personal health admits of being estimated. See LIFE-ASSURANCE.

From birth onwards to old age, health is not uniform; it varies as the body varies, according to wear and tear, and treatment—a sufficiently obvious proposition. At different epochs of life the strain or stress is felt in different parts, falls upon different organs, and issues in proclivity to disorder of their several functions, or in wear or degeneration of the tissues of which they are built. The life of a human being may be divided into the following periods, which will be considered separately in relation to their special physiology, to morbid imminences, and to probable accidents. Rules of guidance will be laid down as to diet, clothing, habits, exercise of body and mind, and all that is conducive to the health of the individual at the different ages.

LIFE-PERIODS.—The following are the periods of life, as they will be here successively considered:—

1. **Intra-uterine life and Gestation.**
2. **Infancy**, the period between birth and the completion of the first dentition.
3. **Childhood**, the period between 2 and 7 years.
4. **Adolescence**, the period between 7 and 14 years.
5. **Puberty**, the period between 14 and 20 years.
6. **Adult age**, the period between 20 and 30 years.
7. **Maturity**, the period between 30 and 45 years.
8. **Turning-time**, the period between 45 and 60 years.
9. **Advanced life**, the period between 60 and 82 years.
10. **Old age**, the period between 82 and 100 years.

1. **The Intra-uterine and Gestation-Period.**—The health, habits, and conduct of the mother during pregnancy modify the future individual considerably. Whatever affects the blood of the mother affects that of her fetus, and *vice versa*.

Alcoholic abuses committed by the mother during pregnancy favour premature delivery, and appear beyond this distinctly prejudicial to the health of the children when these are born alive, the constitutional flaw not showing itself by apparent malnutrition so much as by undue proclivity in them to manifest disorders of the nervous system—chorea and epilepsy in childhood, hysteria and insanity in adult years. Experience shows the hygiene of this period to consist in temperate living. The pregnant woman should avoid excitements of all kinds, take moderate exercise, rise and go to bed early, not alter her habits of life abruptly. She must dress herself appropriately to her state, not so as to interfere with the emergence of the uterus from the pelvis, or so as to limit the movements of the babe *in utero*. See FŒTUS, Diseases of; and MONSTROSITIES.

2. **Infancy.**—The period of infancy may be subdivided into *early* and *late*: *early* comprehending the time from birth to eruption of the first teeth; *late*, that from the commencement to the completion of the first dentition. The leading anatomical features of this age are the large amount

of blood relatively to the solids of the body, the laxity of all the tissues, the disproportionate quantity of component water, and the large relative amount of red blood-corpuscles and of iron, which appears far in excess of that existing in adults.

The circumstance of chief physiological importance is that the greatest growth occurs in the first years of life. Quetelet in his essay, *Sur l'Homme*, shows that the mean average weight of male infants exceeds that of females; boys at birth weighing 3 kilogrammes 20 grammes, and girls 2 kilogrammes 9 grammes. There is no indicator so infallible as the balance to prove whether a baby is or is not being properly nourished. It appears that from birth up to the end of the second day all infants lose weight a little; they do not increase perceptibly till after the end of the first week.

M. Odier states that it is usual to find an infant increase 30 or 40 grammes (461 to 606 grains) *per diem* during the first five months of life, 20 grammes (308 grains) a day from the fifth to the eighth month, and 10 grammes (or 155 grains) daily between the eighth and the twelfth month.

In infantile life all the vital functions go on rapidly. The pulse at birth ranges from 130 to 140 per minute; and to the end of the first year is from 115 to 120. The rate of respiration is from 25 to 30. While the circulation is rapid, the skin, from its softness and vascularity, disperses heat rapidly; the cooling agencies are at a maximum; and the heat-maintaining powers (that is, resistance to depressing influences) are at a minimum. 'The food taken by infants is, in proportion to the weight of the body, from three to six times greater than that taken by adults.'

The perils from without to infant life are mainly derived from cold, those from within result chiefly from improper or defective feeding, and from the over-sensitiveness of the nerve-centres. Young brains and spinal cords are over-alert to impressions received from without. Powers of control become developed as they grow older. The ordinary phrase 'emotional as a young child' expresses a physiological fact. It is not easy to over-feed young infants. If proper food, that is, their own mother's milk, be given them, they get rid of excess quickly enough by vomiting it, and the part not appropriated in growth or maintenance is stored up for future use as fat. Catarrhal diarrhoea and bronchitis, thrush and stomatitis, are due principally to the introduction of micro-organisms in the food or air. Delirium and convulsions attend all febrile disorders. The more closely the evolution of the teeth follows its normal periods the less conscious are infant and mother of their appearance. See DENTITION, Disorders of; and TEETH, Diseases of.

DIET.—Experience proves that no aliment is so appropriate as the milk of the mother, or of a wet nurse aged between twenty-two and thirty-five. Next best to this comes the milk of the ass; and next, again, a mixture of equal parts cow's and ass's milk given by a feeding-bottle. The suckling of her own infant by the mother for nine months is good not only for the child, but for its mother. The uterus passes through its retrograde involution more rapidly, no periodic uterine congestions delay it, and ovulation is deferred. No artificial purgative, oil, gruel, or sugar-water, should be given in lieu of the mother's first colostrum-milk. With respect to the frequency of feeding, and the quantity taken,

the following rules may be laid down. During the first day of life, what with scantiness of the colostrum, mechanical obstacles to suction, and the weakness of the infant's efforts, the child does not extract more than a drachm each time it is placed to the breast. It needs no more, however. During the first week of life it should be nursed ten times in the twenty-four hours, arranging times so that the mother gets six hours' consecutive rest at night. On the second day each suckling should furnish about 5 drachms of milk. On the third day each suckling should furnish about $1\frac{1}{2}$ ounce of milk. On the fourth day each suckling should furnish about 2 ounces of milk. During the first month average-sized infants require and obtain nearly 3 ounces of breast-milk at each nursing, and should be nursed nine times in the twenty-four hours, or receive about 27 ounces of milk a day. During the second month each suckling should furnish $4\frac{1}{2}$ ounces of milk, and the number of feedings may be reduced to seven *per diem*, which allows $31\frac{1}{2}$ ounces each twenty-four hours. At three months old the infant sucks about 5 ounces at a meal, an equivalent of 35 ounces each twenty-four hours; and at four months it extracts as much as $6\frac{1}{2}$ ounces of milk at each meal, which may be again curtailed to six each day, giving $37\frac{1}{2}$ ounces of aliment. This continues to be the quantity of milk and frequency of feeding required of a good nurse up to the end of the ninth month; but the quality of the milk during this period steadily improves, becoming enriched according as the child sucks more vigorously and at longer intervals, a provision fraught with mutual advantage to child and mother.

At the ninth month the child may be gradually weaned, although the age for weaning should be governed by the health of the mother or nurse, the forwardness of dentition, and the infant's own craving for other food. The best time to take for the purpose is the interval or pause after the four lateral incisors are cut, and before the first molars appear.

Dentition, normal order of.—For this subject see DENTITION, Disorders of.

CLEANLINESS AND CARE.—The infant requires washing all over from top of head to sole of foot night and morning every day, and is best, because most quickly, immersed in a tub once daily. Infants who have had convulsions at any period of their lives are, as a rule, better washed all over with a sponge in the lap of their nurse than immersed in a bath, as immersion is apt to frighten them. The water should be the softest procurable; rain-water is best. The temperature of the room during the bath should be between 65° and 70° F.; that of the bath itself, fixed by the thermometer, between 70° and 90° , according to the season of the year. Fixing the temperature of the bath should not be left to the possible indiscretion of a nurse; many a woman's hand will support water at a heat sufficient to parboil a baby.

The nurse should be required not to dawdle over bath or dressing; the former should occupy five minutes, the latter not more than twenty. Little or no soap, or only soft soap, should be employed. The drying should be accomplished with soft dry cloths; and for dusting-powder, to prevent excoriations, fuller's earth cannot be surpassed. Eczema and intertrigo are obviated by due attention to the frequent change of diapers and to cleanliness.

CLOTHING.—No infant ought to be swathed like a mummy; it requires keeping warm, but should not be overweighted with clothes. Its chest must be free to expand, its limbs at liberty to move. From neck to feet it should have woollen garments (with the exception of the napkin) next the skin, since it is impossible to ensure absolute freedom from draughts and rapid changes of temperature. The pernicious custom of heavily weighting an infant's shoulders with clothes, and of leaving the body from the waist to the ankles exposed, cannot be too strongly condemned. The more lightly its head is covered the stronger will be its hair, and the less its susceptibility to catarrh.

GENERAL RULES AND HYGIENIC ADVICE.—Even the youngest infants require sunlight and open air. Due discretion must be employed, however, in sending them out. If the temperature of the external air is about 60° , children may be allowed to go out when they are eight to fifteen days old, after cicatrization of the umbilicus. As soon as they can crawl they should be encouraged to do so, either on a carpet, in a garden, or on a dry sandy pathway protected from wind and open to sunlight. Cold and dark places are specially inimical to them; and when the weather is cold they should be encouraged to amuse themselves on a blanket or soft hearthrug, so as to learn to stretch their limbs and co-ordinate all their muscular movements. They learn first to sit up, then to stand, helped by their arms, against a chair; next to stand without support; and at some period between one year and two years of age should be able to walk about by themselves.

SLEEP.—Infants require sleep by day as well as by night. Very young babies do little else but suck and sleep. As they grow they need and take less and less sleep, and by the time the first dentition is accomplished—three years of age—a child may usually dispense with sleep altogether in the daytime, except a short hour's nap early in the afternoon or between eleven and twelve. The infant should have its own cradle, and the child its own cot, placed close beside the bed of its mother or nurse. In very cold weather, or hard frosts, the cot should be artificially warmed by a hot-water bottle. The sleeping-nursery ought not to be kept warmer than 65° , nor colder than 50° ; while the nearer it is maintained to 55° during the winter months, and 65° during summer, the sounder the child will sleep. The more freely the whole house and nurseries are ventilated, the less prone the infant will be to all infantile disorders.

3. Childhood.—In this period, between the second or third and seventh years of life, the first dentition is accomplished, the second uncommenced. The rate of pulse falls from 115 to 90 per minute, and respiration commensurately. The excretions are all absolutely increased. In the co-ordination of muscular movements and in mental operations great progress is being made. The cerebro-spinal structures, which nearly double in volume between birth and the second year, continue to develop disproportionately to the growth of the trunk and limbs between two and seven. The cellular tissues are loose and vascular still, and the cutaneous and mucous surfaces therefore unduly vulnerable. A notable physiological feature of this age is the readiness of the lymphatic glands to swell upon the slightest irritation, and the general functional activity of all the lymphatic structures. Hence arises a

tendency to eczema and to catarrh of mucous surfaces, diarrhoea, laryngeal and bronchial catarrh, general anasarca, and hydrocephalus; a susceptibility to contagious impressions; and a proclivity to tubercular meningitis, and to functional cerebral disorders like delirium and convulsions. The incontinence of urine, so frequent in early childhood, may be likewise referred to the reflex irritability of the spinal centres characteristic of this age. Undue sexual excitability may occasionally arise and vicious habits be inaugurated. Hence the importance of good nurses and wise supervision cannot be too much insisted on, as also the inculcation of healthy habits and provision of proper amusements and employments.

DIET.—While bread, starch, and flesh-foods are gradually taking the place of cows' milk, they must not be allowed wholly to supplant it. Eight ounces of bread may be reckoned about equivalent in nitrogen-content to one pint of milk, but the former exceeds the latter in carbon. The food must be nutritious and abundant. The error committed is far too often that of under- than of over-feeding. Young children do not require so much variety in their food as adults do, but are greatly benefited by a change in their bread and meal-stuffs, and a dietary not too monotonous. They do not need meat more than once a day, and fish may be substituted for meat, if cream or butter sauce be provided with it, once or twice a week. Milk, bread, porridge, suet-puddings and milky puddings should form the staple of their dietaries; fresh vegetables well cooked, watercress, cooked fruit, and oranges are most useful adjuncts; while the addition of fried bacon, clotted cream, and oil or butter, when the drinking-water is hard, and the tendency of the child is rather towards constipation than otherwise, is now generally understood. It is usually easy and always beneficial to instruct young children to secure an alvine evacuation directly they rise of a morning, and before their bath. Four meals a day are most appropriate—a breakfast at eight, a dinner at twelve, a tea at four, and a supper at half-past six.

CLEANLINESS.—Washing all over once a day, and in the morning, is as necessary as ever; but after first tubbing in hot water between 98° and 100°, the child should stand up and be sponged all over from a basin of cold water, and be briskly dried with a large towel.

SLEEP.—A child should sleep in a cot or bed by itself, but in the same room with its parent or nurse, since it is apt to show any disorder by nocturnal restlessness, delirious talking, or sleep-walking.

Between 2 and 5 most children are the better for twelve hours of sleep out of the twenty-four. At 7 years of age they do not require sleep in the daytime, but should be in bed at seven or half-past seven, and up at six in summer and between six and seven in winter. The best bed for this age is an ordinary iron bedstead, with firm and level wool-and-hair mattresses; not spring beds, which do not adapt themselves so well to light bodies, nor keep them uniformly warm. Cotton sheets, blankets, and counterpane must be used according to season. The day-clothing should be warm, and merino or wool put next the skin.

EXERCISE.—Two things are requisite for healthy growth and development and a happy childhood—a play-room and a garden. Children need a place

like an empty barn, in which they can swing and amuse themselves in wet and wintry, as well as in hot sultry weather, practising those games which are requisite for the schooling alike of their muscles and nerves.

TEACHING.—Teaching such as they need should be conducted on the Kindergarten system; but the main rule for their lives is open air and exercise, the chief objects being to harden their skins, develop their muscles, and teach them self-control, and love and respect for those to whom they render implicit, because well-nigh unconscious, obedience.

4. Adolescence.—The consideration of the period of second dentition, between the ages of 7 and 14, is best prefaced by the order of eruption of the second teeth.

About 7 years the 4 anterior molars (permanent teeth) are cut.

About 8 years the 4 central incisors.

„ 9 „ 4 lateral incisors.

„ 10 „ 4 anterior bicuspids.

„ 11 „ 4 posterior bicuspids.

„ 12 to 12½ „ 4 canines.

„ 12½ to 14 „ 4 posterior molars.

The teeth of the lower jaw usually precede those of the upper. Second dentition is accomplished leisurely, and is therefore usually accompanied by no such grave disorders as mark first dentition; but in nervous children nervous tricks may manifest themselves, as well as marked lack of emotional control. Some are hypersensitive, others contradictory and difficult; and most parents admit that between 7 and 8, if not between 7 and 14, they learn what the characters of their children really are. Physiologically, absorption of the subcutaneous fat goes on rapidly, while the muscles become more developed, the skin gets tougher, its epidermis harder, and it perspires less readily. In our climate the morbid liabilities of this age are to rheumatism, chorea, epilepsy, the exanthemata, and typhoid fever.

Between 7 and 8 the appetite is apt to become capricious; the child physiologically does not require so much fatty food; and, while growing fast and becoming leaner, protests against fat, often while showing a marked longing for fresh fruits, in which nature should be indulged. After 8, however, any marked defect of appetite or loss of weight is suggestive of undue cerebral excitement, attributable to over-study or some infraction of the laws of health.

DIET.—Three good meals a day are sufficient, but four are more advisable. Constipation at this age usually signifies irregular feeding and overloading with pastry or other improper food. Breakfast at eight, dinner at one, tea at five, and supper at eight appears the best distribution. By supper is meant such a meal as growing lads and girls positively need. They require either soup and potatoes, and bread and butter, or some one hot dish of meat or fish; and the drink should be either warm milk or cocoa to about half a pint of fluid: aliment enough is needed to improve the circulation at the extremities and obviate chilblains. Boys and girls may retire to bed within an hour of their supper, which, instead of making them dream, will secure good and refreshing sleep. The greatest dangers at this age arise certainly from defective nutrition and an over-sensitiveness of the skin. Neither wine nor beer should be allowed without medical authorisation.

CLOTHING.—Woollen material should lie next the skin, as it conducts heat less readily than cotton, silk, or linen, and therefore affords the most efficient protection against exposure. A whole chapter could be devoted to the foot alone, and its clothing during its growth and development. The desiderata appear to be length and breadth enough, low heels, impervious soles, old and flexible skins for uppers. Boots for outdoor exercise are advised for children, because their ankles need support; shoes a little later on, because they are cheaper and may be discarded at once when worn out. The same boots should not be worn day after day—they require time to dry properly in damp weather, and the foot at that age profits by change of pressure. During youth the adaptation of clothes to special sports and exercises is far from unimportant to health. For violent muscular exercise, flannel or merino should be worn next the skin, and an easy flannel jacket or over-jersey; both after being used should be hung up to dry and air before being worn again. It is well that youth should be informed how rheumatism is promoted by indolence, neglect of exercise, carelessness in getting overheated, standing about on damp soils, remaining in wet shoes, wearing woollen shirts or underclothing that have been permeated and saturated over and over again with the secretions of the skin.

REST AND EXERCISE.—These are requisite for both body and mind at this age; the duty belongs to parents and schoolmasters to study what is appropriate. We annex, therefore, a table from Friedländer, which shows how the twenty-four hours may be wisely apportioned:—

Age	Hours for			
	Exercise	Work	Leisure	Sleep
7	8	2	4	9 or 10
8	8	2	4	9 or 10
9	8	3	4	9
10	8	4	4	8
11	7	5	4	8
12	6	6	4	8
13	5	7	4	8
14	5	8	4	7
15	4	9	4	7

5. Puberty.—The physiological feature of this period is the more rapid growth of the whole body, and the gradual perfecting in their functions of its several organs. Between 14 and 20 the human organism reaches not only its full size but the completion of its organic endowments. During this period mind and body expand together, but the body develops more rapidly than the mind. Growth proceeds by fits and starts, succeeded by periods of quiescence; seasons affect it, so do supplies of food; boys do not develop so rapidly in autumn and winter as in spring and summer. Girls at this age often fall back, as it were, a little in winter, when they are much more confined indoors, to make a greater push forwards in spring.

It is even difficult for the digestive and assimilative powers to keep pace with the bodily requirements, so that the tendency is for the temperature of the body to fall somewhat, to be ill maintained at the extremities, and for the cold bath to be shunned for lack of adequate reaction in those who are manifestly growing very rapidly.

The heart in some is hardly equal to the task set it, and when it is diseased we perceive both growth and the attainment of puberty retarded. The lungs, again, more often in girls than in boys, do not expand in proportionate ratio with the rest of the body. The body runs up tall, but the thorax remains narrow and flat, and the apices of the lungs approach too closely to each other. The morbid imminences of this age are disorders of the nervous system, chorea, epilepsy, mania, anæmia, rheumatism, and pneumonia. Girls during this period of their lives suffer more illness than boys, probably in consequence of insufficient gymnastic exercises and of over-study in cramped postures. It is the age of all others when good or bad habits of life are formed; the time, too, when the seeds of disease are sown broadcast, to spring up in the after-age of man- and womanhood.

DIET.—Food should be abundant, varied but unstimulating. Three or four moderate meals a day are requisite; if at any period of life fermented liquors are beneficial, now is that time. Light bitter unadulterated table-beer or claret and water should be provided at dinner, but not more than half or three-quarters of a pint of it allowed. If violent exercise has provoked thirst, this may be satisfied with plain water or toast-and-water *ad libitum*. Girls should take cocoa for breakfast, with bread and butter, meat, eggs, bacon, or fish, as much as they like. School dietaries err usually on the side of deficiency. At dinner, as well as substantial meats, fruits, vegetables, and suet and milky puddings are required. Tea should be allowed only once in the twenty-four hours, at six o'clock, and a warm supper be provided at nine o'clock.

CLOTHING.—Nothing need be added to what has been already advised. Without entering into minute particulars, it should be seasonable, rather extra-warm, and offer no uncomfortable restraints. When mothers complain of their daughters' neglected figures, the hygienist retorts, What gymnastic exercises did you require of them? It is the age for exercise of the body as well as of the mind. Boys' spines are straight and girls' backs crooked, because the former use all their muscles and the latter do not. As the body is making its most rapid growth, so the evil of unilateral use of muscles is particularly baneful. Sitting over-long in a slouching attitude will tend to contract the chest, as carrying too heavy weights over the back will spoil the normal spinal curves; so leaning too much on one side, standing too long on one foot, even carrying constantly a pocketful of articles on one side of the dress, will suffice at this age to induce spinal curvature. The daily use of the trapeze, swinging, playing games like *la grâce*, in which both arms are used, badminton, and lawn-tennis, in which arms and legs are employed, and every muscle brought into due action, are quite essential to the proper development of the thorax and the muscles of the trunk. Girls should row and run and ride and swim and skate no less than lads do, in order to become fit mothers for a nation like ours.

The best temperature for a sitting-room is 60°; that for a sleeping-room between 50° and 55°. The hygiene of the bed-room and the bed needs a few words. The temperature of the room should not rise above 65° in summer, or fall below 45° in winter. It must be thoroughly ventilated with a

constant amount of fresh air passing through it during the day. The desiderata for a bed are coolness for the spine, restfulness for the trunk-muscles, and warmth without too great heat or too burdensome a weight of bedclothes. A horse-hair bolster is preferable to a pillow, and a paper-pillow to a feather-pillow; a feather-pillow enwrapping the neck and head heats the upper part of the spinal cord undesirably. Posture in bed is not unimportant. The head should be low, the feet perhaps a trifle raised, certainly not dependent. 'Sleep not on your back, as a dead man,' is a maxim attributed to Confucius; the opposite attitude, on the stomach, is restrictive of the intestinal movements and uncomfortable. It is as well to begin the night lying upon the right side so long as food remains in the stomach, and to turn on first waking upon the left side. The best attitude is probably that crouched one habitually selected. Good advice is to stretch yourself straight whenever you wake, in order to render the circulation of the blood freer. In winter the arms should lie under the clothes, in summer above them.

The cold, or almost cold, bath should be taken by all persons, unless pronounced medically unfit, every morning; with a warm or tepid bath once a week, for cleansing purposes, throughout summer and winter. While the young of both sexes should be encouraged to swim, in seasonable weather, the length of time they stay in the water must be strictly limited according to the temperature.

We abstain purposely from any discussion of the hygiene of mental education. See CHILDREN, Training of.

6. Adult Age.—This is the prime of life, between 20 and 30. Anatomically the body broadens, the chest deepens; for feats of muscular prowess—short, severe labours—it is at its best. The intellectual and cerebro-spinal sexual energies are at their maximum. What the French call the greatest latitude of health and of strength exists at this period; severe strains are supported with apparent ease. In male adults the body gains weight by small amounts for about twenty-eight days, then relapses to its normal average by a sudden crisis, attended by head-heaviness, loss of appetite, and copious discharge of urine or seminal evacuation. It is not a time about which the hygienist has much to say. If the preceding periods of life have been wisely ruled the individual is at his or her best. The morbid imminences directly belonging to this age should be few, and certainly are usually due to direct contravention of the laws of health: to exposure to contagious influences, to irregular living, especially drinking, to excessive strains upon the heart or blood-vessels, to pulmonary inflammations, to contravention of proper sexual relations, to excessive emotional excitement, or to mental worry and loss of sleep.

The guiding rule for this period is succinct enough: '*Sustine et abstine.*' Total abstinence from alcoholic drinks may be recommended. Not only does it favour health, but lessens all the temptations incident to these important years, in which a man carves out his own career. A question not infrequently propounded is, How shall I know when I have eaten as much as is good for me? If individuals are dull or drowsy after a meal they have usually eaten too much; if they can converse, write, or transact business with ease after a meal, they have fed temperately.

Women may be advised to marry not earlier than 21—between 21 and 28—when in our climate they are best fitted to become wives and mothers. Men had better wait till between 28 and 35 before they undertake the responsibilities of being parents. For the generality of men and women we must insist once more on their not giving up out-of-door muscular exercises. An entirely sedentary trade or office-life cannot be a healthy one for either body or mind: the latter appears to suffer most from it—the sense of morality becoming blunted.

SLEEP.—Doubtless different constitutions and individuals differently employed require different amounts of sleep. As nothing dulls the intellect and weakens the recuperative faculties more than too much sleep, except over-feeding and drinking at this age, so few things are more certain than that a man may rise too early for making the best use of his twenty-four hours. John Wesley's advice in this matter is worth recording. He writes that any man can find out how much sleep he really requires to repair his nervous system by rising half an hour earlier every morning until he finds that he no longer lies awake at all on going to rest in bed, or wakes up until it is time for him to get up. Six to eight hours is usually ample for healthy adults, with nine hours every seventh day. The mistake too often made is that of endeavouring to make up for over-hard mental efforts by over-long sleep hours. Mental over-fatigue is to be repaired not by sleep, but by bodily exercise in the open air. Exercise directs the blood-flow from the head towards the muscles, and renews the appetite. As we have pointed this out as the suitable age for marriage, we may mention some things which conduce not slightly to healthful and happy marriages: parity of station, compatibility of temper and tastes, and no marked disproportion either in age or size.

7. Maturity.—The body has now reached its maximum weight and solidarity, and the period is that of maximum endurance. Men reach their full weight at 40; women later, sometimes not till 50. The morbid tendency is towards obesity or dyspepsia, both alike being determined by a too sedentary town-life, and by daily occupation in close, ill-ventilated, and badly lighted chambers. Now are perceived the first attacks of gout; while visceral degenerations and atheroma of arteries may manifest themselves—events all of which may be delayed, if not wholly prevented, by attention to the laws of health. It is desirable that each individual should pay heed to his weight at this age, since this indicates whether or no he is living wisely. When, however, men are engaged in trades or professions, there is no more difficult task than to maintain their weight at this age, the *juste milieu* referred to being a hard matter to secure. The advice given by Celsus (lib. 1, cap. 1) cannot be surpassed in force or brevity: '*Sanus homo qui et bene valet et suæ spontis est nullis obligare se legibus debet; hunc oportet varium habere vitæ genus, modo ruri esse, modo in urbe, sæpiusque in agro, navigare, venari, quiescere interdum; siquidem ignavia corpus hebetat, labor firmat.*' As to diet, clothing, and habits, we need add nothing to what has been already advised for a previous age; but on exercise of body and mind there is much to be written.

A good rule is laid down by Lynch, too, in his *Guide to Health* (p. 290), that the lean should exercise *ad ruborem*, i.e. to glow-point, or until

their bodies and spirits are heated, for that will fatten them; and the fat *ad sudorem*. The more luxuriously a man lives, the more exercise, and the more active exercise, he needs. Want of it, and the costive habit thus superinduced, may, as Kotzebue observes, extinguish the divine flame of genius and seriously impair the intellectual powers. Hypochondriasis and hysteria are the special punishments of ease and affluence and indolence. Obviously a portion of each day should be set apart for those who can take it. In the households of the wealthy a gymnasium is at least as important as a bath-room. The chest should be expanded by clubs and dumb-bells; swinging on the trapeze, and hanging by the arms and legs, may be recommended. Again, before forenoon or midday meal, an hour's ride or walk must be obtained; and a third time in the day an hour and a half's exercise—fencing, or walking, or rowing—should be arranged before bedtime, in the spring and summer seasons. A great point is to vary the exercise by every means at hand: to change the set of muscles called chiefly into play upon different days, as Celsus advised: to swim, ride, fence, sail, row, shoot, fish. Bodily exercise should not be undertaken immediately after a heavy meal; nor should those who have sweated themselves violently sit down at once to a full meal—at least an hour's rest should intervene.

A few words of advice may be given as to what is proper and profitable in mental work, and what is improper and likely to prove detrimental to the cerebral organs. Most brains suffer more from rest than overwork. Exercise is as essential for the healthy nutrition of the cerebral as it is for that of the muscular tissue, and without regular employment daily up to fatigue-point no high quality of intellectual condition is ever attained. Fret, hurry, worry, and the endeavour to accomplish some task in too short a time, is what wearies and wears the thinking organ; but what damages it is always its imperfect nutrition, the insufficient repair of its waste after its active employment. It is a matter of observation that feeble brains, those constructively defective, or those damaged by accidental injury or by disease, most speedily suffer both from overwork and from actual disease. The education of the half-witted and of congenital idiots is a difficult problem as well as a disheartening task; that they admit of some improvement is proved, but directly their daily exercises are discontinued they fall back. Immature brains are doubtless more vulnerable and require more rest, more sleep, and more diversion than fully developed ones. Again, the mere degenerative changes in the blood-vessels and capillaries incident to disease and old age interfere with the nutritive changes requisite for the most perfect intellectual operations. Hence it is easy to point out a true pathological foundation for epileptic insanity and senile dementia, and to perceive why poorly fed children should suffer from over-pressure in schooling.

The cultivation, however, of the human mind, and the determination of what is best for its sound development and maintenance, belong to education, not hygiene. Let it suffice to say that the *mens sana in corpore sano* depends as much upon the judicious training and education of the intellectual centres, as it does upon their minute structures and sound nutrition. The best intellects are built on good foundations; the education of the cerebral

centres begins with the first special-sense impressions made upon them, and, we may hope, does not terminate only with this life. There is still as much to be learned in the training of the brains as there is in that of the muscles. True excellence is only to be reached after much striving, and can be attained only by gradual steps, and slowly.

8. **The Turning Period.**—This period of life, which lies between 45 and 60, is also known as the *grand climacteric* or *middle age*. The skin wrinkles. Up to 60 years of age the skull may continue to increase in size, principally at its anterior part, by enlargement at the frontal sinus; after 60 the skull-cap loses weight, and the brain may waste, but gets tougher and firmer. The heart grows a little larger, and its walls are thicker. The lungs grow denser, a change common to every tissue of the body. The hair grows grey; the features sharpen; the sight alters; and the hearing grows dull. Pressure and wear and tear begin to tell at every part. Upon the blood-vessels their effects are more marked in males than in females, because ordinarily the former labour harder than the latter; further, the death-rate of men is greater than that of women at this age. As the sexual powers decline, which they do by a quick descent between 46 and 63, the intellectual powers increase, so that mentally there is often exhibited a marked increase of vivacity and agreeableness, more noticeable in men than in women. In the latter the cessation of the catamenia is attended usually by some rejuvenescence, attributable to their recovering a little embonpoint. It is an age, however, at which women kick rather, and become restless and uneasy, the change of life being attended in many by a renewal of their juvenile tempers, as between 7 and 14, and occasionally by a revival of their youthful ailments, such as eczema, skin-eruptions, and various neuroses, insomnia, hysteria, and sometimes epilepsy. In character, whatever obstinacy exists reaches its climax.

MORBID IMMINENCES.—The inflammatory disposition is lessened, but there is a tendency to venous plethora of the abdominal viscera, and towards vicarious hæmorrhages. Gout assails its victims with well-characterised attacks. New-growths, simple and malignant, tend to demonstrate themselves, and rheumatoid arthritis to appear. At this time a man first experiences a reluctance to stoop, prefers a carriage to riding on horseback, and perceives each change of the weather affect him.

HYGIENIC RULES.—At the menopause women should be advised to abstain, as a rule, from alcoholic drinks, and to avoid highly spiced and seasoned dishes. They may be recommended to take meat not more than once daily, and to live chiefly on farinaceous food, milk, eggs, vegetables, and fresh fruits. A tablespoonful of lime-juice taken twice daily occasionally for a week or ten days at a time has a salutary, depurating effect upon both stomach and kidneys, and clears the tongue when this is foul in the morning. Riding and walking exercise are highly appropriate, but very violent muscular efforts should be avoided. If the individual be thin, and growing thinner, the clothing should be extra warm. Flannel abdominal belts may be worn advantageously in all seasons, but especially in autumn and winter.

Both sexes should avoid emotional excitement, and the stimulation of waning sexual abilities.

Prolonged exposure to wet and cold is sure to be seriously resented. Hot or Turkish baths, succeeded as they should be by the cold plunge or douches to remove the lassitude otherwise provoked, are very beneficial, and taken once a week may be safely indulged in throughout the year. It becomes increasingly important as the subcutaneous fat gets absorbed, and the skin wrinkles, to keep its pores clean and open and capable of perspiring.

9 and 10. **Advanced Life, and Old Age.**—The period of advanced life—60 to 82, and old age, from 82 upwards, may be advantageously considered together. When a man turns his toes out much in walking and treads upon the whole base of his foot, when he is always stopping and turning round to look back, he is already old. The sagacious 'boots' at an inn can tell a man's age by the state of his shoe-leather.

'*Senectus ipsa morbus insanabilis.*' Some degenerate earlier than others, but the decline of life is characterised in all human kind alike by an indurating condition of every tissue, diametrically opposed to the cellular softness and laxity of infancy. The capillaries thicken, the arteries harden, the nutritive changes proceed more slowly. The muscles waste; the subcutaneous fat lessens; the blood becomes poorer and paler; the skin dry, sallow, and wrinkled; further, it gets less vascular, and the mucous surfaces become relatively more so. The teeth loosen and fall out; the gums recede from them; and the digestive juices fail. The arteries become atheromatous and calcareous, lose their elasticity, and are liable to fibrinous thromboses, or to embolic pluggings; and while they tend to block up at one part, their coats may split and yield to pressure, bulge out, and form aneurysms or dilatations in other directions. Hence happen apoplexies, brain-softenings, and senile gangrenes. The heart up to an uncertain period grows progressively larger and more muscular, to meet the obstacles offered to the circulation; but finally it, too, degenerates, and its walls grow thinner and dilate. The air-cells of the lungs lose their elasticity, and progressively enlarge; then merge into each other; and become emphysematous at the edges of the lobes where least supported. Emphysema implies degeneration of capillaries and diminution of aerating surfaces; and as the pulmonary area becomes thus lessened, the right heart becomes hypertrophied and dilated.

The dryness and lessened secretion of the skin cast harder work upon the kidneys in eliminating water, and increase the disposition to catarrhal fluxes from the nasal passages, the bronchi, and the intestines. Thus, while there is a constant predisposition to irritation of the skin from its dryness, and to eczema from scratching and rubbing it, the other morbid imminences towards bronchial catarrh and diarrhoea very closely follow the direction given them by the season of the year, and greater or less degree of external cold. The bladder grows thicker with age, and its capacity is less; the prostate gland enlarges. Few persons after 60 pass seven hours in bed without requiring to micturate. The pulse feels firmer and fuller; fills quickly after food is taken, but falls in frequency and flags in power in a marked degree after fasting. It is a far less trustworthy indicator of the gravity of any febrile disorder, or of degrees of asthenia, than it was in youth or middle age; and it fails to point to the

practitioner the nearness of death, unless he have large experience of it.

There is a default of reaction manifest in advanced life, so that all acute disease is clinically less easy of recognition, and the beginning of the end is therefore apt to pass unobserved. The thermometer warns the doctor of changes which old people do not notice themselves, but which it may be of considerable importance to notice. A slight elevation of temperature means much in old age, and should be heeded accordingly. The slightest change excites a young child; nothing seems to move the old man. In extreme old age life is little more than vegetative existence; the individual eats and sleeps and dreams. The sleep the aged get by night seldom rests or satisfies them. Memory is one of the first mental faculties to become impaired, but finally every sense and every faculty fail. Up to 75 the strong of both sexes usually retain their digestive powers, and a fair amount of mental and muscular vigour. Later on, indecision, inconsequential reasoning, self-distrust, uncertainty as to facts, delusions of sight and hearing, restlessness, day-dreams, night-wandering, too often prove that the old are no longer what they once were in intellect, and testify to the brain-degenerations belonging to senile dementia.

HYGIENIC RULES.—A prime necessity for old age is warmth: nothing kills the aged so certainly as cold. It is of first hygienic importance after 75 that the individual should be loved and cared for; old people do not, perhaps cannot, take care of themselves.

Those who live longest, and enjoy the fullest measure of activity, are those who do not over-tax their stomachs when their teeth begin to fail them, and who adapt their aliment to their enfeebled powers of mastication, by having their food properly cooked. A moderate amount of wine or some other stimulant often cheers and comforts old people, and is better for them than overloading their stomachs with milk and farinaceous foods.

Great attention should be paid to the functions of the bowels and of the skin. Galen pointed out that old people should not suffer their bowels to remain costive beyond two days; on the third they should take some gentle purge, such as by experience they have found adequate. A hot bath once a week, and a hot foot-bath every night, may be advised. A short nap after breakfast and before dinner is the natural habit of the aged. Further, their clothing should be additionally warm, and their chambers night and day be heated. They should be encouraged to go out in the open air only in seasonable weather; and, when they are equal to it, should take a little walk on a dry gravel path in some warm locality, sheltered from north-easterly winds. All change and cheerful society are good for them. If their purses admit of it, they should follow the swallows to warm winter-quarters. If they must winter in England, let them shut themselves up throughout the season in a well-warmed house.

SUMMARY.—Advice for every age may be thus briefly given: for infancy and childhood—*sustine*; for adult years—*sustine et abstine*; for old age—*sustine* again.

The hygienist, however, seeks not to lengthen out the days of age and decrepitude; his art is not to prolong life beyond its natural term, though this may come subordinately, but to render its period of

activity and utility longer. Some cynic observes that we have pointed out very few habits as worth cultivating, the truth being we believe what we have insisted on—that most bodily habits need resisting. Individual health is attained by self-denial; habits imply self-indulgence. REGINALD SOUTHEY.

H. MONTAGUE MURRAY.

PERSPIRATION, Disorders of.—See SUDORIPAROUS GLANDS, Diseases of.

PERTUSSIS (*per*, signifying excess; and *tussis*, cough).—A synonym for whooping-cough. See WHOOPING COUGH.

PESTIS (Lat.).—A synonym for plague. See PLAGUE.

PETECHIÆ (*petigo*, an attack, eruption; Ital. *Petechie*, fleabites).—SYNON.: *Peticula*; Fr. *Pétichies*; Ger. *Petechien*.

DESCRIPTION.—Petechiæ are small crimson or purple spots in the skin, resembling those that result from the bite of a flea, and due to minute hæmorrhages. See PURPURA.

PETIT MAL (Fr.).—A term applied to attacks of epilepsy which are of short duration and slight intensity. See EPILEPSY.

PETRI-DISH.—A circular glass dish, about 10 c.mm. in diameter, with perpendicular sides, usually 1.5 c.mm. deep, loosely covered by an inverted dish of similar form but of slightly greater diameter. It is used in the plate-cultivation of bacteria.

PETRIFICATION.—See CONCRETIONS.

PFÆFFERS, in Switzerland.—Simple thermal waters. See MINERAL WATERS.

PHAGEDÆNA (*pháγω*, I eat away).—A form of ulceration, which rapidly destroys the surrounding parts. See BUBO; GANGRENE; ULCER AND ULCERATION; and VENEREAL SORE.

PHAGOCYTOSIS (*pháγω*, I eat; and *κύτος*, a corpuscle).

DEFINITION.—A term expressing the property possessed by certain animal cells, called 'phagocytes,' of taking into their substance solid particles, which may either be rejected, be used by the cell for its nutrition, or, when the solid mass is living, may destroy the cell.

Phagocytosis, from this wide definition, is thus a process not limited to diseased conditions of the animal body, but is a part of a general property possessed by cells in animals of every grade, invertebrates and vertebrates. The cells which act as phagocytes are not highly differentiated: they are not, like the muscle-fibre or the nerve-cell, organised to perform special functions, but they possess the characteristics inherent in undifferentiated protoplasm. Two of the chief properties of these cells are the amoeboid movement or power of contractility of the protoplasm, and the power of digestion. They are, moreover, very sensitive to stimuli, both chemical and physical, which diminish or increase their movements, or which attract them to one spot. To a certain extent they show a selective power, that is, they refuse to take in some solid particles; but how far this power is generalised in the different cells which act as phagocytes it is

at present impossible to say. The relation of phagocytosis to disease is in part discussed in the article on IMMUNITY. The anatomical facts which have been discovered by a study of phagocytosis will alone be discussed in the present article. For convenience, it is best to consider the subject under two headings—(1) *physiological*, and (2) *pathological phagocytosis*.

1. *Physiological Phagocytosis*.—Examples of this occur in both the most lowly and the highest animals. The amoeba takes into its substance solid particles which, if suitable for the nutrition of the organism, undergo digestion, and, if unsuitable, are ejected after remaining in the substance of the protoplasm for some time. The ciliated animalculæ (of which Paramœcium may be quoted as a type) also take into their substance particles of the nature just mentioned, which undergo a similar process. This intracellular digestion is also a feature in Hydra, sponges, and other allied animals. In the higher animals there are many examples of this phagocytosis, for example, in the absorption of fat in the small intestines, in which the globules are taken up by the epithelial cells and then by the leucocytes, by which they are conveyed to the lymph-stream; in the absorption of bone during ossification and in old age by the osteoclasts; and in the absorption of the branchiæ and tail of the tadpole during its transformation into a terrestrial animal. These processes are performed by cells, playing the part of scavengers. It is sufficient to mention these facts to bring them into line with what more nearly concerns disease, namely, pathological phagocytosis.

2. *Pathological Phagocytosis*.—This is observed when a living organism is injured mechanically or infested by a parasite, or when an inert foreign body is introduced into its substance. It is a battle between the host and the parasite, in which in some cases the host, in some the parasite, gains the upper hand. Parasitism may not inconveniently be divided into two varieties: in the one, the parasite, by the bulk of its growth, may be fatal to the host by interfering with the essential functions of the organism, or of a vital organ; in the other, the parasite acts on its host not so much by the bulk of its growth as by the poisonous products which it excretes or forms from the tissues of its host. Infective disorders in man and the higher animals, so far as we know them, belong chiefly to the second variety of parasitism; to the first variety belong some of the cases of parasitism in the lower animals; perhaps also in man (e.g. animal parasitism). Whatever truth there may be in this division of parasitism, it must be borne in mind that it is not yet clear that every noxious parasite is capable of secreting products which are poisonous to the host. To illustrate this question of parasitism in the animal kingdom and its relation to phagocytosis, the description given by E. Metchnikoff in his *Leçons sur la Pathologie comparée de l'Inflammation* (1892) will be adhered to.

Commencing with the lowest in the animal grade, the *unicellular organisms*, such as the amoeba, it has been mentioned that the solid living particles (diatoms, bacteria, &c.) ingested by them may serve as food; but some of the living bodies absorbed, instead of being digested, may actually produce a fatal disease. Thus, as Metchnikoff has shown, the amoeba may take into its substance a microsphaera (an organism composed of nucleated round-cells,

multiplying by division) which multiplies to such an extent as to kill the amoeba. This is an example of fatal infection of a unicellular organism by a parasite. Examples of similar parasitism in other lowly plants and animals are well-established. In some instances the living bodies, diatoms and bacteria, are ingested and digested by the organism, in other instances the ingested living body multiplies and destroys its host.

The study of phagocytosis becomes more complicated in *multicellular organisms*. Of the three layers of cells of which the majority of these organisms are composed, namely, the ectoderm, endoderm, and mesoderm, it is the last to which the property of phagocytosis is eventually limited in the process of evolution. This limitation of the phagocytosis to the mesodermic cells is attained only gradually. The sponges, animals composed chiefly of ectoderm and endoderm, with a well-developed mesoderm, protect themselves against harmful bodies by means of their contractile ectodermic cells, but also by the phagocytic power of the mesodermic and endodermic cells. In them the mesodermic cells play a large rôle in the normal digestion of the organism. Some of the Coelenterata possess no mesoderm, and in these (Hydra, for example) the endodermic cells, which have the property of sending out amoeboid processes and of performing the normal digestion of the organism, play the rôle of phagocytes; in other similar animals, the ectodermic cells are also phagocytes. Such animals are without any vascular system. This is also absent in the Medusæ, which, however, possess a mesoderm differing from that of the sponges in the fact that the mesodermic cells play no part in the normal digestion of the animal. These mesodermic cells are, however, the phagocytes. They surround and attack harmful substances introduced into the substance of the animal, and may unite together, forming *plasmodes*, an example of the formation of giant-cells low down in the animal scale. In all animals higher than the medusæ, namely, echinoderms, worms, vertebrates, this formation of plasmodes, or giant-cells, by the union of mesodermic cells is very common, the plasmode in some instances completely surrounding the foreign body or parasite, as in fig. 1.

FIG. 1.—A Giant-cell in Actinomyces enclosing the clubs of the fungus (700 diam.). Ruffer.

The Classes Mollusca and Arthropoda possess a vascular system, filled with a liquid containing colourless cells. These cells are mononuclear; their protoplasm is in one variety granular, in another hyaline. They act as the phagocytes of the animal. Numerous experiments have shown that, after a lesion of a part of the animal, these cells accumulate near the injured spot as they do in an 'inflamed' area in warm-blooded animals. A similar accumulation occurs around inert foreign bodies introduced into the animal; and the cells also take up pigment-granules injected into the tissues

(Haeckel, 1862). The best example of infection in such animals has been brought forward by Metchnikoff as occurring in the water-flea, *Daphnia magna*, which in a pond was found infested with a kind of yeast-fungus, *Monospora bicuspidata*. At certain periods an epidemic of this disease will kill off nearly all the daphniæ in the pond. A study of the process shows that the ripe spores of the fungus are eaten by the daphnia, and pass through the intestinal wall into the body cavity. Here the elongated spores become surrounded by the leucocytes, and one of two events may happen. The spores may rapidly increase in number and fill the body-cavity, eventually destroying the life of the daphnia; or, becoming surrounded by leucocytes, they undergo degeneration, so that they are killed or are not fatal to the daphnia.

FIG. 2.—A phagocyte of the *Daphnia* containing two undegenerated spores of the *Monospora*. (Metchnikoff, Virchow's *Archiv*, vol. xvi.)

FIG. 3.—A spore of the *Monospora* enclosed by phagocytes, and undergoing degeneration. (Metchnikoff, *ibid.*)

In both cases there is a struggle between the leucocytes and the germinating fungus: in the first, the fungus overcomes the resistance of the leucocytes; in the second, the leucocytes surround and finally digest the spores of the fungus.

In the very young tadpoles of the lower amphibia (urodeles) phenomena similar to those occurring in mollusca have been observed by Metchnikoff and others. Thus, after a slight injury to the non-vascular fin of the tadpole, the amoeboid cells collect at the injured spot, the fixed cells of the tissue taking no part in the process. In older tadpoles, when the blood-vessels are developed in the fin, there is still this accumulation of amoeboid cells at the injured spot; but there are also the phenomena of inflammation such as are observed in the higher animals, namely, acceleration of the blood-stream, &c. As Metchnikoff points out, both the phenomena in the very young and those in the older tadpole must be classed as 'inflammatory,' although in one case there is no vascular change. Similarly, the phenomena following an injury or an infection which have been described as occurring in invertebrate animals possessing a mesoderm must be classed as inflammatory; not as belonging to a completely developed process of inflammation, but as forming one of the stages in the evolution of the inflammatory process in the animal kingdom.

Phagocytosis in the *higher animals* is a part of inflammatory and of infective processes. All primary inflammatory processes are infective, that is, due to a living infective agent. The study of the nature of inflammation and that of the process of infection are in reality to be conducted on the same lines, both being due to the introduction into the healthy organism of a harmful agency, which may either remain localised in its action, or may become generalised.

The cells which act as phagocytes are derived from the middle layer of the embryo (mesoderm), and are some varieties of leucocytes, the endothelial cells of the vessels, and the elements of the splenic pulp. The endothelial cells possess the power of contractility in many animals. In leprosy they not uncommonly contain large masses of the *Bacillus*

lepræ. In rabbits inoculated intravenously with the *Bacillus tuberculosis*, these cells take up the bacillus; a similar phagocytosis occurs with the bacillus of swine-erysipelas. The endothelial cells and the elements of the splenic pulp are also macrophages.

The varieties of leucocytes, including those possessing phagocytic action, are described on p. 156.

Leucocytes can digest suitable particles taken into their substance. This digestive power is a property inherent in all original cells. In some cases of infective disease, the living bacteria have been observed to undergo this digestion in the phagocyte; they lose their protoplasm, leaving the investing membrane, which also finally disappears; and they also lose the property of being stained by some aniline dyes, such as vesuvine. Examples of this are found in recurrent fever in the ape, and in the *Streptococcus erysipelatis* in man (Metchnikoff). Some of the bacteria may be digested and others not, the latter infecting the organism generally. This has been observed in tuberculosis and in swine-erysipelas.

It has been a question whether the bacteria taken in are living or not; but it has been proved by Metchnikoff that they are in some cases not only living, but virulent, since a single phagocyte of a pigeon (an animal refractory to anthrax) containing anthrax-bacilli has been separated, and the bacilli cultivated in a suitable medium, proving on inoculation fatal to mice, &c.

The two varieties of leucocytes which act as phagocytes appear in some instances to be selective in their action. Thus in man it is the neutrophile leucocyte which takes in the *Streptococcus erysipelatis* and the gonococcus; the mononuclear leucocyte remaining inactive. On the other hand, the mononuclear leucocyte is the phagocyte of the *Bacillus lepræ*; the neutrophile variety remaining inactive.

Instead of digesting the bacterium, the phagocyte may prevent it developing. Thus the spores of anthrax injected into fowls and frogs (which are refractory to the disease) commence to germinate, but are taken up by the leucocytes. If, however, the body-temperature of the fowl be lowered by cooling the animal, or that of the frog increased by warming, the activity of the leucocytes is diminished, and the spores then germinate rapidly, the bacilli invading the whole body.

In other cases the leucocytes do not take in the infective agent, as in mice and guinea-pigs infected with anthrax, and in pigeons and rabbits infected with fowl-cholera; and according to Metchnikoff the more virulent the infection, the less phagocytosis occurs.

Why the leucocyte, possessing as it does the property of absorbing solid particles, refuses in one instance to act as a phagocyte, or why in another only one variety of leucocyte acts as a phagocyte, although both are present, is perhaps in part explained by what has been described as *chemiotaxis* (see IMMUNITY). Certain substances have the power of attracting leucocytes, others actually repel them—positive and negative chemiotaxis. Thus most bacteria, living or dead, as well as their chemical products (toxins), papain, and leucine attract leucocytes; while the most virulent bacteria, strong solutions of sodium and potassium salts, alcohol, chloroform, glycerine, bile, quinine, and

jequirity repel them. Some substances act in a neutral manner.

Chronic infective processes.—The best examples of such processes are tuberculosis and leprosy. The formation of miliary tubercle has been ascribed to the proliferation of the fixed cells of the organ affected, that is, the alveolar cells of the lungs, the hepatic cells, &c.; leucocytes playing but little part in the formation. This is the view usually held. From a study of tuberculosis in the early stage, produced by the intravenous injection of the bacillus in rabbits, Metchnikoff has concluded that in the liver the tubercle is formed not by the hepatic cell, but by the phagocytes, the mononuclear leucocytes and the endothelial cells. The agglomeration of phagocytes forms the tubercle, the fusion of some of the cells forming giant-cells; the tubercular nodule is therefore purely mesodermic in origin, and is produced by the phagocytes accumulating to attack the bacilli. The polynuclear leucocytes readily absorb the bacilli, but soon die, being absorbed by the mononuclear leucocytes (the macrophages). The macrophages are more resistant to the bacilli, and may destroy them. In leprosy, also, Metchnikoff considers that the cells containing the bacilli are phagocytes struggling against their invasion; the leprous nodule would thus be ranged with the tubercular nodule as one of purely mesodermic origin.

SIDNEY MARTIN.

PHANTOM TUMOUR.—SYNON. : Hysterical Tympanites; Spurious Pregnancy.

DEFINITION.—A peculiar enlargement of the abdomen, occurring in females belonging to the hysterical class. It is supposed by the patient to be an actual tumour, or to be due to pregnancy, but it can be made at once to disappear by placing her under the influence of chloroform.

DESCRIPTION AND DIAGNOSIS.—The phantom tumour is characterised by a more or less general prominence of the abdomen forwards, varying in degree. The enlargement may attain a considerable size, but is always quite symmetrical. The projection is most marked about the middle of the abdomen, and usually a depression or constriction is observed below the chest and above the pubes. It is rounded, smooth, and quite regular, presenting a uniform soft feeling, quite distinct from that of gaseous distension, fluid accumulation, or a solid mass. The enlargement is peculiarly movable, as a whole, from side to side. There is no sense of true fluctuation. Percussion yields a resonant note, but not usually excessive, and it may be of a muffled character. On examination *per vaginam* nothing abnormal can be detected, such as would be associated with ovarian or uterine enlargements, or with pregnancy. Should there be any doubt whatever as to the nature of the supposed tumour, it may be at once cleared up by placing the patient under the influence of chloroform or other anæsthetic, when the swelling immediately disappears, the abdomen becoming quite flat; but it gradually returns, even before the patient returns to consciousness, on the removal of the anæsthetic. There is no pain or tenderness in connection with the enlargement; nor are any symptoms due to pressure or other causes observed: while the patient usually presents distinct signs of the hysterical condition. There ought, therefore, to be no difficulty in the diagnosis of a phantom tumour. What is the actual cause of the enlargement is

by no means clear, but most probably it is due to a kind of paralysis of the intestines depending upon disordered innervation.

TREATMENT.—In a patient having a phantom tumour, the general and medicinal treatment for hysteria is that principally called for. She should be constantly impressed with the fact that the enlargement is not really a tumour, and is of no consequence. The condition is by no means easy to get rid of, but for this object galvanism may be applied to the abdomen, or, in obstinate cases, the patient may be put repeatedly under chloroform. The use of pressure, by means of an abdominal bandage or elastic apparatus, might be serviceable in some cases. The bowels should be kept freely opened.

FREDERICK T. ROBERTS.

PHARYNX, Affections of.—**SYNON.:** Fr. *Maladies du Pharynx*; Ger. *Krankheiten des Pharynx*.—In this article the affections of the pharynx will be described under the following headings:—

1. Acute Inflammation of the Pharynx, p. 1216.
2. Chronic Inflammation, including Hypertrophic Pharyngitis, and Atrophic Pharyngitis (*Pharyngitis sicca*), p. 1216.
3. Acute Infectious Phlegmon, p. 1217.
4. Erysipelatous Pharyngitis, p. 1217.
5. Gangrene of the Pharynx, p. 1217.
6. Retro-pharyngeal Abscess: (a) acute primary form, (b) chronic secondary tubercular form, p. 1217.
7. Syphilis of the Pharynx, p. 1218.
8. Tuberculosis of the Pharynx, p. 1219.
9. Tumours, Innocent and Malignant, p. 1219.
10. Pharyngocele (pressure-pouch), p. 1219.
11. Stenosis of the Pharynx, p. 1220.
12. Foreign bodies, p. 1220.
13. Neuroses of the Pharynx, p. 1220.
14. Pharyngomycosis, p. 1221.

1. Acute Inflammation of the Pharynx.—**SYNON.:** Acute Pharyngitis.—This affection is commonly catarrhal in type, and associated to a greater or less extent with acute inflammation of the tonsils. It may owe its origin (1) to exposure to cold and damp; (2) to a rheumatic or gouty constitution; (3) to the poison of an infectious disease, especially syphilis and scarlet fever; (4) to certain drugs; and (5) to a direct irritant, such as burns and scalds, injury, hot condiments, raw spirits and tobacco-smoke. It is probable that most of the cases classed under (1) and (2) are caused by micro-organisms, the condition appearing at times to be of an infectious nature.

SYMPTOMS.—There is at first a dryness and feeling of heat, stiffness and discomfort in the pharynx, which is increased to actual pain on swallowing. Soon the secretion, which was checked for a time, increases in amount and becomes mucoid and sticky, or muco-purulent in character. The patient has a constant desire to hawk and clear the throat. The soft palate, tonsils and walls of the pharynx are generally congested and swollen, and the uvula appears oedematous, and greatly increased in size. The inflammation has a marked tendency to pass upwards into the naso-pharynx, where it may involve the mucous lining of the Eustachian tubes, or downwards into the larynx, causing hoarseness or temporary loss of voice. Unless there is much tonsillar involvement the constitutional symptoms, elevation of temperature and increase of pulse-rate, are slight.

Frequent attacks of acute inflammation may give rise to the chronic form of pharyngitis, and in adults acute inflammation, particularly in smokers and drinkers of raw spirits, is apt to supervene on a pre-existing chronic pharyngitis. It is to be borne in mind that acute inflammation of the pharynx may, in its early stages, be confounded with other far more serious diseases—e.g. diphtheria, scarlet fever, &c. If the constitutional disturbance be out of proportion to the local inflammation the practitioner should be on his guard lest he mistake for a simple acute pharyngeal catarrh a pharyngitis toxæmic in origin and due to a grave infectious disease.

TREATMENT.—In the uncomplicated cases the inflammation tends naturally to run a short course. A saline aperient, placing the feet in hot water, and a dose of Pulv. Ipecac. Co. (gr. viij to xij) are generally sufficient. A fomentation round the neck affords relief if there be stiffness and pain, and slight enlargement of the cervical lymphatic glands. Steam inhalations (Tinct. Benzoini, ʒj to the pint of hot water) are useful, if there be laryngeal involvement (p. 745). In cases that are distinctly rheumatic in origin salicylate of sodium, and in sthenic gouty inflammations colchicum with citrate of lithium, will be indicated. Guaiacum or krameria lozenges may be given as soon as the secretion from the mucous glands has become free and the acute inflammatory swelling has subsided.

2. Chronic Pharyngitis, including hypertrophic and atrophic pharyngitis (*Pharyngitis sicca*). Chronic inflammation of the pharynx may be the sequel of repeated acute attacks, or may occur in persons who have not suffered from acute pharyngitis, but who are great smokers, or drinkers of spirits, or who habitually overstrain the voice, as in the case of clergymen, auctioneers, costermongers, &c. It is frequently found in association with chronic naso-pharyngeal catarrh. In certain cases the inflammation appears to be of a chronic catarrhal nature, in others there is little to be seen but hypertrophic enlargement of the lymphoid nodules of the pharynx. No useful purpose is served by describing these types as separate conditions, since commonly they are found in association, though one or other may predominate.

The term 'atrophic pharyngitis' or 'pharyngitis sicca' is frequently applied to a chronic condition in which the mucous membrane of the pharynx is thinned, smooth and dry from deficient secretion of mucus; and complaint is made of abnormal dryness of the throat. This condition may be found in association with atrophic rhinitis, but frequently occurs independently. In chronic catarrhal cases the mucous membrane of the pharynx is relaxed; it has a slightly congested appearance, and dilated venules are seen on the posterior pharyngeal wall, which is often partly hidden by sticky plugs of tenacious mucus. The soft palate, tonsils, and uvula frequently present a similar condition. In the hypertrophic or granular form numerous small red gelatinous-looking granules are seen on the posterior wall of the pharynx. These are due to an hypertrophy of the lymphoid tissue of the pharynx which is in general collected around the muciparous glands. Frequently there is also seen a lateral fold of thickened mucous membrane and submucous tissue lying behind the posterior pillar of the fauces and simulating a third faucial pillar (*lateral hypertrophic pharyngitis*). This condition

of hypertrophic pharyngitis in some cases gives rise to no symptoms; in others, particularly in debilitated, neurotic or dyspeptic individuals and in women at the menopause, great complaint is made of loss of voice, heat, a perpetual desire to clear the throat and a certain amount of pain and difficulty in swallowing. In children a condition of enlargement of the lymphoid nodules in the pharynx is often seen and is invariably associated with post-nasal 'adenoid' vegetations.

TREATMENT.—So many cases of this affection are dependent upon a general constitutional condition that attention must always be first directed to the patient's general health. Thus, if gout, rheumatism, dyspepsia, portal engorgement, anæmia, or a general neurotic condition be present, appropriate general treatment must be combined with topical applications to the pharynx. Smoking and over-use of the voice must be prohibited; and rest, bracing air, and tonics enjoined. Topical applications are of limited value. For the removal of tenacious mucus, a solution of bicarbonate of sodium and borax (of each ʒj to eight ounces of warm water) may be employed as a spray, and iodised glycerine (℞ Iodi, gr. vj; Potassii Iodidi, gr. xij; Ol. Menth. pip. ℥viii; Glycerini, ad ʒj), or glycerine of tannic acid may be applied to the pharynx by means of a camel's-hair brush. The most satisfactory results in the treatment of chronic pharyngitis are obtained in the cases in which the granular lymphoid hypertrophy is well marked. The destruction of the granular nodules by means of the galvano-cautery gives marked and often lasting relief. Some cases of chronic pharyngitis defy all treatment, particularly those in which the patient declines to give up the habit of smoking. It is a fact difficult to explain, but undoubted, that destruction with the galvano-cautery of granular lymphoid nodules not infrequently cures the loss of voice from which patients may suffer. Spraying with a 5-per-cent. solution of hydrochloride of cocaine renders the application of the electric cautery quite painless. In atrophic cases (pharyngitis sicca) the local application of glycerine diluted with an equal quantity of rose-water relieves the sensation of dryness in the throat.

3. Phlegmonous Pharyngitis (Acute infectious phlegmon of the pharynx).—This most formidable affection is, fortunately, of rare occurrence. It may be traumatic in origin, but in not a few instances no history of injury can be obtained. It commences as a severe acute pharyngitis; the mucous membrane becomes deeply congested and oedematous, the lymphatic glands enlarge and the neck increases in bulk and becomes infiltrated and brawny. The constitutional symptoms are intense, and there is great elevation of temperature and rapidity of pulse-rate. Deglutition is impossible; and pharyngeal oedema along with laryngeal involvement (oedema glottidis) cause extreme dyspnoea or even death from suffocation. In other cases death results from septicæmia or exhaustion. At the *post-mortem* examination there are found intense diffuse purulent infiltration of the mucous membrane and submucous cellular tissues and the general appearances of septicæmia. In marked examples of this terrible condition treatment is unavailing, and death always results.

4. Erysipelatous Pharyngitis.—By many erysipelas of the pharynx is held to be identical in origin with phlegmonous pharyngitis; but, though

there is much to be said in favour of this view, the clinical differences are so great that it is well for the present to consider them two distinct pathological conditions. Erysipelas may attack the pharynx primarily or may be secondary to facial erysipelas, the latter being of far more frequent occurrence. The symptoms are practically those described as occurring in phlegmonous pharyngitis, but are much less severe. Suppuration is very exceptional in erysipelas. The process may spread to the larynx, causing oedema and intense dyspnoea. There is rapidity of pulse, high fever, and marked constitutional disturbance; albuminuria occurs in almost every case, and not infrequently delirium and coma. The diagnosis is easy in cases secondary to erysipelas of the face, but is extremely difficult in the rare primary examples of the disease. Erysipelas, though frequently fatal, is, as a rule, recovered from. When death results it is in general due to heart-failure, acute oedema of the larynx, or pneumonia.

TREATMENT.—The patient may be given ice to suck, and a cloth wrung out of iced water and frequently changed may be wrapped round the neck. Nourishing fluid food with brandy and digitalis (especially when the pulse is feeble) and quinine must be administered. Tincture of perchloride of iron is, in the writer's opinion, useless. Should symptoms of dyspnoea arise due to acute oedema of the larynx, free scarification of the mucosa may be tried; and if this fail rapidly to relieve the dyspnoea, intubation of the larynx or preferably tracheotomy must be at once undertaken.

5. Gangrene of the Pharynx is rare. It may be a sequel to either of the two last-described affections or may be met with in syphilitic disease of the pharynx. It is a very rare complication of diphtheria, scarlet fever, measles, typhoid fever, and small-pox. In greatly debilitated patients it may supervene on divers forms of ulceration of the pharynx. The gangrene may occur in patches, or a large portion of the pharyngeal wall (diffuse gangrene) may be involved: in the former type recovery commonly takes place after separation of the sloughs; in the latter extreme fetor of the breath, enlargement of the cervical lymphatic glands, profound septicæmic symptoms with high fever and rapid pulse occur, and death from heart-failure or septicæmia results.

TREATMENT.—Inhalations of steam charged with some volatile antiseptic (carbolic acid, thymol or eucalyptus) may be used; or the pharynx may be sprayed with a solution of biniodide of mercury (1 to 3,000) or permanganate of potassium, or be painted with iodised glycerine. Nourishing fluid food must be administered, and stimulants and digitalis will be needed to combat the intense prostration. Treatment is, as a rule, of little value, most cases terminating fatally.

6. Retro-pharyngeal Abscess.—This consists of a collection of pus between the posterior wall of the pharynx and the bodies of the cervical vertebræ. Two types of the affection, differing greatly in their origin, course and prognosis, must be separately described: (1) the acute primary; (2) the chronic, commonly tubercular, type.

(1) Acute primary retro-pharyngeal abscess is the more frequent and more formidable type. It may be met with at any age, but the great majority of cases occur in very young children, between the third and twenty-fourth months of life. In these young patients it always commences as a suppurative

adenitis, affecting definite lymphatic glands, which are placed in front of the upper cervical vertebræ on either side of the middle line of the neck and between the posterior pharyngeal wall in front and the prevertebral aponeurosis behind. These glands are well marked in infants and very young children, but diminish greatly in size, or even disappear entirely, after the seventh year. This suppurative lymphadenitis is the result of infection with micro-organisms, almost always streptococci, which have gained entrance through some small abrasion of the mucous membrane of the pharynx or naso-pharynx, or even of the face (cracks and fissures, or possibly as the result of eczema). Though the vast majority of cases of acute retro-pharyngeal abscess commence as lymphadenitis, the inflammation may commence in the connective tissue as a result of mechanical injury or some ulceration of the pharyngeal mucous membrane. Acute abscesses in the case of adults are of this variety, but such are quite exceptional. Acute retro-pharyngeal abscess tends to occur chiefly in debilitated children, and in those who suffer from syphilis, tuberculosis or acute infective diseases, in which the resistance of the tissues to microbic infection is greatly lowered. In certain cases, however, children apparently perfectly healthy are suddenly attacked. The pus is commonly very foetid. The condition develops rapidly; there is high fever, marked snoring at night, and pain in the throat, greatly increased by swallowing. In certain cases food taken regurgitates through the nose. Dyspnoea becomes urgent; cyanosis appears; there is stridor and often cough. The cervical lymphatic glands are enlarged and the neck is held stiffly, as all movements are attended with much pain. On inspection of the pharynx—provided that there be no difficulty in opening the mouth, as is sometimes the case—the posterior wall of the pharynx is seen deeply congested and bulged forwards; and fluctuation may be made out, almost always in the pharyngeal swelling, and sometimes externally in the neck about the angle of the jaw. In some cases the bulging occurs chiefly in the naso-pharynx, in others in the laryngeal region; in these latter dyspnoea from laryngeal oedema is particularly threatened.

(2) The chronic, commonly tubercular, form is the less frequent type of retro-pharyngeal abscess. It is almost always dependent upon tubercular disease of the bodies of the cervical vertebræ, though it may in rare instances be due to cold abscess arising in connection with the prevertebral glands, unassociated with vertebral caries. The affection is free from the marked constitutional disturbances described in connection with the acute form. Its course is chronic; there is little or no elevation of temperature or pain referred to the pharynx. Commonly symptoms of disease of the bodies of the cervical vertebræ precede the formation of an abscess; and there is generally rigidity and deformity of the neck. In contradistinction to the acute form this affection is found in children or young adults, and is quite unusual in infants under twelve months old. The pharyngeal swelling and fluctuation are, as a rule, easily recognised. The prognosis, owing to the almost constant association with vertebral caries, is unfavourable.

TREATMENT.—It must be borne in mind that if the abscess burst spontaneously death almost inevitably results, owing to the pus gaining entrance to the respiratory passages and causing suffocation

or septic pneumonia; and that even before bursting of the abscess can occur a fatal result may be caused by spasm of the glottis, oedema, or asphyxia, due to the bulk of the abscess obstructing the lower pharynx. Surgical treatment is therefore always demanded. In very urgent cases a vertical incision may be made into the abscess by a knife introduced from the mouth; but this method is objectionable, owing to the risk of pus gaining access to the air-passages, and the probability of septic infection of the abscess-cavity occurring, owing to the open wound communicating directly with the mouth. If this method be employed at all it must be with the child so placed that the pus will tend to run out of the mouth rather than into the larynx, i.e. the mouth must be inclined downward. It is far better to make an external incision along the posterior margin of the sterno-mastoid (Chiene), and after incising vertically the deep cervical fascia and drawing forward the great vessels of the neck, to puncture the abscess and dilate the opening with sinus-forceps. A drainage-tube is then introduced, and in cases secondary to tubercular disease of the vertebral bodies the latter may be attacked directly, any carious or necrotic portions being removed. This operation has the great advantage that it can be aseptically carried out. It must be invariably undertaken in all chronic tubercular cases, and is to be recommended as a rule in the acute type, except perhaps in those instances in which, owing to the abscess being on the point of bursting, or to extreme dyspnoea, the result of oedema of the larynx, the surgeon fears to administer anæsthetic. In such cases incision of the abscess through the mouth is to be performed.

7. Syphilis of the Pharynx.—Syphilis may attack the pharynx in the primary, secondary, or tertiary stage, and may be acquired or of congenital origin.

Primary chancre may occur on any part of the pharynx, but the tonsil is by far its most frequent site. The lesion is seldom characteristic, induration being frequently absent or little marked, and ulceration often very pronounced. Not infrequently a correct diagnosis is only arrived at on the appearance of secondary manifestations of the disease.

Secondary syphilis commonly affects the pharynx, though the parts that suffer most are the tonsils and anterior faucial pillars. An erythema especially involving the above-named parts, and causing shedding of the swollen epithelium, gives place to erosions, and several of these may coalesce to form large irregular or serpiginous patches. These erosions chiefly affect the free margin of the soft palate, the tonsil and pillars of the fauces, and much less frequently are situated on the posterior wall of the pharynx.

Mucous tubercles (*plaques muqueuses*) are common in the same situations. Such ulceration as occurs in secondary syphilis is almost always superficial, and is generally the result of the breaking down of mucous tubercles. The ulcers have a greyish base and well-defined edges, and though they extend superficially they remain shallow. The suffering caused by these lesions seldom exceeds a moderate degree of soreness, thus differing markedly from the intensely painful tubercular ulcerations. For secondary syphilitic ulcers and erosions, in addition to mercurial treatment, the lesions should be touched twice daily with a 2-per-cent. solution of chromic acid.

In *tertiary syphilis*, the pharynx may be the seat of a localised gumma, and the usual situation of this lesion is the posterior wall of the upper half of the pharynx, most commonly in the naso-pharynx, where the swelling is hidden from view by the soft palate. When such a gumma breaks down a deep excavated ulcer (not infrequently involving the vertebral bodies) is seen, with a foul discharge, sloughy base and circular margin, external to which is a ring of intensely congested mucous membrane. Owing to the great loss of substance which these ulcers occasion, much deformity from cicatrization is prone to occur. When the soft palate and the posterior pharyngeal wall are simultaneously involved, adhesion between these parts may result. Stenoses of the pharynx, described below, commonly owe their origin to tertiary syphilis. A puckered radiating cicatrix on the posterior wall of the pharynx is not infrequently found as a result of a healed tertiary ulcer. Gummatous ulcers are wonderfully amenable to treatment with iodide of potassium.

8. Tuberculosis of the Pharynx.—This is a somewhat rare affection and is scarcely ever met with as a primary disease, being almost always secondary to pulmonary or laryngeal tuberculosis. In such cases it is a late symptom and frequently leads to a rapidly fatal termination. It is not uncommon to find a more chronic form of tubercular disease of the pharynx in patients suffering from lupus of the face or nasal passages. The disease presents itself in the pharynx in (1) an acute and (2) a chronic type. The disease commonly commences in the soft palate or pharynx as a thickening of the mucous and submucous tissue in which tubercles develop. Soon these break down into ulcers which are shallow and increase in size superficially by coalescence one with another. Around these ulcers, which have greyish cheesy bases, numerous miliary tubercles are seen covered by gelatinous transparent mucous membrane. These miliary tubercles are characteristic of the disease. Perforation of the soft palate or pharyngeal wall is quite unusual. The affected parts become infiltrated and stiff, and all movement is inefficiently performed. Pain is extreme. Swallowing may cause such agony that the patient refuses food rather than attempt the act of deglutition. There ensue the usual symptoms of advanced tubercular disease—wasting, fever, night-sweats, and marked prostration, end ng in speedy death. In the more chronic form, sometimes described as lupus of the pharynx, there are fewer tubercles, much nodular thickening, and a more chronic callous form of ulceration. In both forms of pharyngeal tuberculosis it is the rule to find the neighbouring lymphatic glands enlarged and caseous.

TREATMENT.—In the most advanced cases palliative treatment alone is possible, e.g. spraying the throat with a 2-per-cent. solution of cocaine hydrochloride or painting the part with a solution (15 per cent.) of menthol in olive-oil or paraffine. In all other cases an attempt at eradicating the disease must be made, for though permanent cure is exceptional, marked improvement often results for a time, at least, from curetting with a sharp spoon the cocaineised pharynx or soft palate, and then applying daily a solution (25 to 75 per cent.) of lactic acid. The general treatment of tubercular disease will be at the same time undertaken.

9. Tumours of the Pharynx, Innocent and Malignant.—The pharynx is not a common seat of tumours. Among innocent growths papillomata alone are not infrequently found. They may be situated on any part of the mucous membrane, most frequently on the margins of the palate, fauces and uvula, and on the posterior wall of the pharynx. Fibromata, lipomata, nevi and cysts are very rarely met with. These tumours give rise to symptoms only when they are of considerable size. Fibromata and lipomata tend to assume a pedunculated appearance. Such tumours as well as papillomata may generally be cut off with scissors, or, if of large size, removed by the galvano-cautery snare. Sessile growths must be enucleated after dividing the mucous membrane underneath which they lie.

Malignant tumours occur more frequently in the pharynx than do innocent growths. Sarcomata are rare, epithelioma being the form of malignant tumour commonly met with. The site of the epithelioma is commonly on the lateral or posterior wall of the pharynx, but primary pharyngeal epithelioma is much more uncommon than an extension of the disease from tongue, tonsil or soft palate on to the walls of the pharynx. In epithelioma pain is a prominent symptom, and the act of deglutition causes so great suffering that the patient refuses food rather than endure the agony attendant on swallowing it. There is a sensation as of a foreign body in the pharynx, intense pain in the ear if the cancer be on the lateral wall of the pharynx, enlargement of the cervical lymphatic glands, and putrid blood-stained mucoid secretion which flows from the mouth. There is frequently difficulty in opening the jaws sufficiently widely to enable inspection of the pharynx to be satisfactorily undertaken. In sarcoma of the pharynx the above symptoms may be present but in a less marked degree, the bulk of the tumour rather than the pain it causes occasioning the chief part of the symptoms.

When ulceration has occurred in malignant disease it sometimes closely simulates the appearance found in tertiary syphilitic disease, and the administration of iodide of potassium may be required to clear up the diagnosis.

TREATMENT of malignant disease of the pharynx consists whenever possible in removing the cancer, taking care to cut widely clear of the disease. The operation is not infrequently successful in sarcoma, but in epithelioma recurrence of the disease is almost invariable. The tumour may be attacked from the mouth, but this gives in all cases insufficient access to the growth. Sub-hyoid or lateral pharyngotomy is a much superior method, and one or other should in all cases be employed (for details concerning these procedures works on operative surgery must be consulted). Epithelioma of the pharynx in the condition in which it commonly comes under the notice of the surgeon, with considerable glandular involvement, is as a rule inoperable, or at any rate operations undertaken for its cure prove futile. In such cases palliative treatment is all that remains to the practitioner. This may be summed up as consisting of spraying with a solution (2 per cent.) of cocaine prior to the taking of food, morphine freely administered to dispel the agonising pain, and feeding *per rectum* when deglutition can no longer be performed.

10. Pharyngocoele is the name given to a peculiar bag-like diverticulum frequently described as an oesophageal pouch (pressure-pouch of the

cæphagus). Almost always, however, these pouches have their origin at the lowest part of the pharynx and should be described in connection with this part. They are rare, but not so rare as is generally held to be the case. Their origin is still very obscure. In a typical example a pouch is found starting from the pharynx just above the commencement of the cæphagus and passing downwards behind the gullet and in front of the bodies of the vertebrae. In general the pouch bulges towards the left side, though the orifice by which it opens into the pharynx is accurately mesial and is commonly slit-like with its long diameter transverse. These pouches are by many held to be due to the pressure exercised by the food in deglutition forcing outwards a hernial protrusion of mucous membrane and submucous tissue. This pressure of the bolus of food undoubtedly tends to enlarge the pouch when once it is formed, but the constant position of the orifice points strongly to the origin being traceable to some congenital malformation; commonly there is no muscular tissue in the wall of the pouch. Pharyngocæles rarely cause symptoms until middle life, when the sac reaches a size sufficiently large to give rise to difficulty in deglutition. The patient may at the beginning of a meal swallow well; soon deglutition becomes difficult and some of the food is returned, usually but slightly changed, but sometimes decomposed. The more the pouch is filled with food the greater becomes the difficulty in deglutition. In certain cases, especially where the pouch is large (i.e. 4 inches long and capable of holding from 2 ounces to a quarter of a pint of fluid), a softish tumour is appreciable in the neck and can be emptied by external pressure. In time the symptoms become so marked that death from starvation threatens. In order to appreciate the information obtainable from the passage of a bougie, it must be remembered that at one time the bougie may pass without difficulty into the stomach (say 16 inches or more) and at the next essay may be caught in the pouch and its further progress arrested. In the slighter cases, in which the pouch is small, pressure on the neck has been recommended during deglutition to prevent food entering the sac. Palliative treatment, however, is of no avail. Extirpation of the sac has been in several cases safely performed with the most gratifying result. It can be carried out by an incision on the left side of the neck along the anterior margin of the sterno-mastoid muscle. A sound introduced into the pouch through the mouth greatly facilitates the procedure.

11. **Stenosis of the Pharynx** is commonly the result of the cicatricial contraction of syphilitic ulcerations, but may owe its origin to burns, scalds, tubercular ulceration or to traumatism. The most frequent form is the result of adhesions, commonly partial, rarely complete, between the soft palate and neighbouring parts, particularly the posterior wall of the pharynx. Stenosis of the laryngeal portion of the pharynx is fortunately much more uncommon. In complete adhesion of the soft palate to the posterior pharyngeal wall nasal respiration is impossible and the mouth becomes dry from mouth-breathing. The senses of smell and taste practically disappear and speech is indistinct. Should the soft palate be dragged downwards and adhere in part to the base of the tongue, the narrowing may become so extreme that only a small rubber tube may be able to pass through the stric-

tured opening. In such instances swallowing becomes a matter of the utmost difficulty and the patient must be fed with fluids or semi-solids only. Examples of stenosis such as the above are easily recognised. In the diagnosis of narrowing of the lower part of the pharynx the laryngoscope will be needed. Stenosis in this situation is most serious, respiration and deglutition being both gravely compromised; and there is great danger of asphyxia due to the impaction of a bolus of food during its prolonged passage through the narrowed tube of the lower pharynx. Complete stenosis in this region is obviously incompatible with life.

TREATMENT.—As a rule examples of partial adhesion of soft palate to the posterior wall of pharynx and to the base of tongue are best left alone. If the former be complete it may be divided, and an india-rubber ball, which can be inserted into the orifice and blown up *in situ*, may be used to prevent re-adhesion. In extreme cases of the latter form the stricture may be ‘nicked’ by cutting upwards into the soft palate, and bougies frequently passed or a tube worn for some time. The tendency to re-contraction is very great. Stenosis of the lower part of the pharynx, when marked, demands operative treatment owing to the risk of asphyxia. A preliminary tracheotomy having been performed, the stricture is incised in a backward and upward direction with the aid of the laryngoscope, and dilatation by bougies must be carried out regularly. In all the above cases treatment is most disheartening owing to the great tendency to re-contraction that is present. It is, however, remarkable how little stenosis due to partial palatal adhesion seems to distress many patients.

12. **Foreign Bodies** in the pharynx are as a rule substances which the patient has attempted to swallow. Their removal is in general easily effected by means of the finger, within reach of which they commonly lie, or by curved forceps. They are frequently fish-bones, or splinters of bones of mammals or birds; not infrequently, however, in gluttonous individuals, a large bolus of food—commonly meat—becomes impacted in the lower pharynx, and may rapidly cause death from asphyxia. Such may demand the instant performance of a laryngotomy to save life, after which the bolus of food may be extracted by the mouth or pushed down into the stomach by means of a bougie. Foreign bodies in the pharynx, e.g. coins, nuts, fruit-stones, &c., which children have previously had in their mouths, may commonly be got rid of by holding the little patients up by the legs and stimulating coughing by tickling the throat with a feather, or by shaking the child so held head downwards.

13. **Neuroses of the Pharynx** may be divided into (a) motor; and (b) sensory.

(a) **Motor neuroses** may be paralytic or spasmodic. *Paralysis* of the soft palate is commonly diphtheritic in origin. Paralysis of the pharyngeal constrictors is more commonly the result of hysteria, or of central origin as in bulbar paralysis, though it may occur as a sequel of diphtheria. Frequently the paralysis is unilateral, though it may affect both sides. Paralysis of the pharyngeal constrictors causes difficulty in deglutition when unilateral, and when bilateral the act of swallowing cannot be performed and the patient must be fed with a tube. The treatment of the paralysis depends upon its cause. In post-diphtheritic paralysis in which the

prognosis is very good, strychnine administered internally is of undoubted benefit, and some good may result from local application of the faradic current.

Spasm of the pharynx is seen as a very formidable symptom in hydrophobia and sometimes in tetanus (see TETANUS), but apart from these terrible maladies it is almost always of functional origin. It is common in hysteria, in which condition difficulty in deglutition due to this cause is not infrequently complained of, and may also be observed in neurotic individuals, particularly in association with tonsillitis and chronic pharyngitis. The treatment must be directed to the cause.

(b) *Sensory neuroses*.—Anæsthesia of the pharynx may be due to hysteria, diphtheria, bulbar paralysis, or general paralysis. It may be complete or partial, unilateral or bilateral, and is commonly found in association with paralysis of the larynx and soft palate. Should the larynx be sufficiently anæsthetic to permit of food entering it the symptoms are urgent, otherwise they are in general but little noticed. Hyperæsthesia and abnormal sensations of heat, foreign body, pricking, smarting, spasm, or obstruction in the pharynx are chiefly noticed in hysterical patients, though they may be met with in gouty patients, in dyspeptic alcoholics and hypochondriacs. The most common form of paresthesia is that in which a neurotic female complains of a lump in the throat (*globus hystericus*).

Neuralgia is uncommon and may be very severe. It is most frequently seen in neurotic women in whom there is some slight abnormality, e.g. chronic pharyngitis.

14. **Pharyngomycosis Leptothricia**.—The *Leptothrix buccalis* is a fungus which may be considered a normal inhabitant of the human mouth, and it is difficult to understand why in certain cases it takes on an abnormal activity of growth and forms milk-white patches on the tonsils, fauces, tongue, posterior third of the soft palate, or posterior wall of pharynx. The scrapings from these patches show, on microscopical examination, the long threads of the fungus with stratified epithelial cells and amorphous granular detritus. The patches of growth are commonly circumscribed, somewhat firmly adherent to the mucous membrane, and raised above its surface. There is no surrounding inflammation. The symptoms caused by this condition are in general trivial; heat, irritation and dryness in the throat are complained of, and sometimes a degree of dysphagia or cough. There is no fever, increase of pulse-rate, pain, or other constitutional symptom, and the absence of these differentiates the condition from diphtheria. When the tonsils alone are affected, the condition might be mistaken for chronic lacunar tonsillitis; a closer examination will, however, show that the adherent milky-white patches are very different from the yellow cheesy foul-smelling pellets that lie in and are easily turned out of the tonsillar crypts. Carious teeth, chronic tonsillar enlargement, dyspepsia and impairment of the general health, all seem to predispose to the immoderate growth of the fungus. The treatment commonly advised consists in removing the patches, preferably by burning with the galvano-cautery, but recurrence is the rule, and this method is very unsatisfactory. It is an undoubted fact that most cases left alone get well without topical treatment. It is therefore wiser to attend to the general health, enjoining sea-air and

tonics, and to pay particular attention to the digestive functions and to the hygiene of the mouth. A visit to the dental surgeon, with extraction of stumps, filling of carious teeth and removal of the tartar, followed by amputation of the tonsils or destruction of their crypts, will in many cases prove effectual in curing a condition which has defied many applications of the galvano-cautery.

HERBERT F. WATERHOUSE.

PHIMOSIS (φίμωσις, I confine).—SYNON.: Fr. and Ger. *Phimosis*.—A morbid condition of the penis, in which the prepuce cannot be drawn back over the corona of the glans. See PENIS, Diseases of.

PHLEBITIS (φλέψ, a vein).—Inflammation of a vein. See PHLEGMASIA DOLENS; and VEINS, Diseases of.

PHLEBOLITH (φλέψ, a vein; and λίθος, a stone). A concretion formed in a vein. See CONCRETIONS; and VEINS, Diseases of.

PHLEBOTOMY (φλέψ, a vein; and τέμνω, I cut).—A synonym for venesection. See BLOOD, Abstraction of.

PHLEGM (φλέγω, I burn; I am inflamed).—A popular name for sputum or expectoration. See EXPECTORATION; and SPUTUM, Examination of.

PHLEGMASIA DOLENS (*Phlegmasia*, inflammation; and *dolens*, painful).—SYNON.: *Phlegmasia Alba Dolens*; Pop. White Leg; Fr. *Phlegmasia Alba Dolens*; Ger. *Phlegmasia Dolens*.

This is a disease having very distinct characters and easily identified. It has, therefore, been long familiarly known both to the profession and the public. Except in lying-in women it is uncommon, few medical men seeing well-marked or characteristic cases of it under any other circumstances; and it is for the most part as a disease of the puerperal state that it has been the subject of study and investigation.

ÆTIOLOGY.—Phlegmasia dolens affects both sexes, and no age is exempt from it. It has been met with in the new-born infant as the result of a septic condition. It may attack any part of the body, but one or other of the lower limbs is the ordinary seat of the disease. Occasionally it seizes one lower limb first and then the other, or may extend from the one to the other. The well-characterised disease, as it affects lying-in women, is an affection of one or other of the lower limbs, very rarely of both. The left leg is far more frequently affected in the puerperal state than the right; and the left leg is supposed to be more frequently affected than the other under whatever circumstances the disease occurs. In lying-in women the comparative frequency of this affection, and of several other morbid conditions on the left side, is believed to depend on the circumstance that the parts on that side of the pelvis are more frequently subjected to pressure and bruising than the parts on the other side. Tears of the cervix, for example, are somewhat more frequent on the left than the right side. This probably arises from the comparative frequency of the right lateral obliquity of the uterus throwing the direction of the uterine power of labour across the mesial line to the left side of the pelvis. The disease affects multipare more than

primiparæ. It is prone to recur in successive confinements.

From the variety of circumstances under which phlegmasia dolens may occur it will be easily apprehended that it may arise in any period of pregnancy or of the puerperal state, but the usual time of its appearance in lying-in women is the second week after delivery. It rarely commences in the first week, less rarely in the third; seldom subsequently in the puerperal state.

The special proneness of lying-in women to this disease probably depends on the changes in the blood, viz. the increase in the amount of water and in the number of the white corpuscles, and the diminution in the amount of the albumen and in the number of red corpuscles, which prevails during pregnancy, and on the natural formation of thromboses in the uterine sinuses at its termination.

Besides the puerperal state, other conditions render a patient liable to phlegmasia dolens. Among these are convalescence from fever—especially typhoid—dysentery, disease of the rectum, malignant disease of the uterus, uterine fibroids, arrest of menses, and malignant and tubercular disease generally. Occurring in connection with any of these conditions the disease may vary greatly in severity, from being scarcely recognisable to its utmost degree of intensity. But its liability to severity is not the same in all circumstances. For example, in connection with malignant diseases of the womb it is often very slight and chronic. The complaint has been frequently observed to affect the leg of the side corresponding with a previously commenced pleurisy. Wallich and Pinard regard this pleurisy as probably due to small pulmonary infarctions.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances referable to phlegmasia dolens vary, especially in the presence or absence of thrombosis of the veins. Phlebitis and thrombosis are, however, generally found, with more or less associated inflammation of connective tissue and of the lymphatics. The intravenous blood-clots vary in extent, sometimes occurring as high as the vena cava inferior. They vary in appearance, being more or less decolourised, more or less softened, or even in parts diffident. They may be adherent to the veins, partially organised or separable from them. They may entirely block the veins, or may allow the passage of blood between them and the wall of the vein or through their substance as by a tunnel. In recent cases the clot adheres to the internal coat of the vein, which is blood-stained. The coats are thickened and inflamed, and the surrounding cellular tissue is also sometimes specially hardened. In cases complicated with pyæmia there may be found suppuration of the clots, and other appearances observed in that condition.

PATHOLOGY.—Various theories, which reflect the pathology of the times at which they appeared, have been held concerning the nature of phlegmasia dolens. The disease was ascribed to a metastasis of lochia by many pathologists, and by others to a metastasis of milk. The discovery of the lymphatics in the last century led to the first attempts of a truly scientific kind to solve the mystery of the nature of this affection, the suggestion being that it arose from their injury and obstruction. The next attempt to account for this disease was based on the important discovery of the thrombosis of the

veins of the affected limb. This was erroneously assumed to be an invariable or essential condition of the disease, which was accordingly now regarded as phlebotic. But the occurrence of the lesions regarded as essential, the phlebitis and thrombosis, without the development of the characteristic appearances of the affected limb; and, on the other hand, the occurrence of the characteristic appearances without the simultaneous presence of the phlebitis and thrombosis, demonstrated the insufficiency of the phlebotic theory. The next theory to be mentioned is a sort of retrogression to humoral pathology. It alleged that a morbid condition of the blood, of undefined nature, is, along with phlebitis and thrombosis, necessary for the production of the disease.

Another theory is that the disease, as it is seen in lying-in women, is essentially a parametritis, probably of septic origin—that is, an affection of the cellular tissue, commencing, indeed, in the close neighbourhood of the womb, but extending to remote parts, and, it may be, prevailing in them, while the original inflammatory affection of the womb and its immediate neighbourhood has diminished, or even disappeared. Parametric inflammation extends in a similar manner occasionally as far as the cellular tissue around the kidney. When it extends to a limb, it is believed to be the cause of the phlegmasia dolens, and to have the phlebitis and lymphangitis with their secondary thromboses as its consequences.

The divergence of the views as to the causation of phlegmasia is probably in part due to the fact that there is more than one variety of the disease. We may distinguish a thrombotic form in which the clotting of the blood in the vein is either a primary condition or due to some mild degree of septic infection, and a cellulitic or parametric form in which the cause of the thrombus is to be found in the inflammatory changes occurring outside the vessel wall. The occurrence of apyrexial cases of endometritis, due to the presence of the streptococcus *in utero*, shows that the absence of rise of temperature does not exclude some degree of septic infection; and the fact that in the great majority of cases of white leg there is some degree of fever tends to show that a mild form of septic infection is the commonest exciting cause. Further evidence in favour of this view is to be found in the fact that Widal and Chantemesse have demonstrated the presence of streptococci in the clot in the affected veins in the uterus and broad ligaments in three cases complicated by phlegmasia alba dolens. It may well be urged that every case of true white leg in which both the veins and the lymphatics are affected, as distinguished from what may be termed a swelled leg where the veins alone are involved, is the result of some degree of septic infection at the time of delivery. That this is so in the parametric variety, associated as it often is with extensive involvement and sloughing of the subcutaneous tissue, there can be no doubt.

In the primary thrombotic form of phlegmasia the occurrence of the thrombus is usually attributed to the increased tendency of the blood in the puerperium to coagulate, acting in conjunction with dilatations of the veins and a feeble circulation. Further bacteriological investigations are required to prove that this form of white leg can occur independently of septic infection.

The great barrier to progress in our knowledge

of the nature of phlegmasia dolens is the rarity of *post-mortem* investigations, and the sometimes doubtful character of the evidence they afford. Very few unexceptionable *post-mortem* investigations have ever been made in this disease. Such an inspection must be made in an early stage, and in a patient dying accidentally from some cause unconnected with the disease of the limb. Now, the disease is not only not fatal in an early stage, but it might be asserted that by itself it is not fatal at all—that death, apparently from it, occurs only in complicated cases—in such as run an extraordinary and rare course.

SYMPTOMS.—As a rule, phlegmasia dolens is preceded by a slight access of feverish phenomena, seldom by a distinct rigor. There is also sometimes an indefinite malaise for a day or two, before the pain in the limb is complained of. Another premonitory symptom is described, but it is certainly not always present—namely, pain and tenderness in the region of the womb, especially affecting that side of it corresponding to the limb about to be swollen.

The first definite announcement of the disease is generally acute pain along the course of the femoral vein, or in the calf, or above the ankle. In these situations the thrombosed vein can frequently be felt, but not invariably, for sometimes the tenderness, sometimes the swelling, prevents its being made out; and sometimes this thrombosis is absent, at least in parts where it can be felt through the skin. Soon the pain and tenderness extend over the whole affected parts, which may be the whole limb, and often a feeling as of aching in the bones is complained of. The pain is sometimes along the internal saphenous vein, which may be traced by the finger till it dips to join the femoral.

Simultaneously with the complaint of pain, or within a day or two after it, swelling appears, which gradually spreads and increases in hardness. This swelling is not like ordinary oedematous or anasarctous swelling in the sensation it communicates to the hand of the physician, or in the history of its commencement and progress. When it commences, and again as it disappears, it may be, comparatively to its perfect state, soft, and it may pit on pressure; but when, a few days after its appearance, it is fully developed, it is very tense, and nearly as hard as a solid india-rubber ball, and does not pit on pressure. The swelling may appear at once all over the limb, but frequently it commences above and spreads downwards. Sometimes the inverse course is followed. It not rarely affects only the lower parts of a limb, very rarely the upper parts only. It does not affect the posterior more than the anterior surface of the limb. It rounds off the figure of the limb, but does not distend the skin or destroy the form so entirely as anasarca. If the skin is pricked the exudation is a coagulable lymph. Vesicles or blisters are at times present on the skin. Occasionally there is an erythematous blush over parts of the limb; but this is not common, and it may be confined to a narrow strip along the course of a subcutaneous vein or lymphatic.

In a characteristic and fully developed case, such as is frequently observed in the puerperal state, the limb presents a remarkable appearance. The swelling affects the labium and hip and the whole limb, only rarely rising higher. The form of the limb is partly retained, but its features are all

rounded and nearly lost in the swelling. Its colour is white, and hence the name occasionally used of 'white leg,' and formerly of 'milk leg,' when it was supposed to be due to a metastasis of milk. But besides being pale, it is glossy; or its surface resembles that of polished marble, and the disease is sometimes called 'marble leg.' In the milder cases the swelling is less, and softer, and may be confined to a part of the limb.

The limb may be kept in an extended attitude, or it may be slightly flexed at the joints. Movement of it causes much suffering, and the power of voluntary motion is almost completely lost while the disease continues.

After the disease has lasted nine days or thereabouts, it generally makes no further progress, but recedes, the pain and swelling diminishing. The rate of this recession varies very much, being probably more or less directly in proportion to the restored permeability of the vessels. In about 68 per cent. of the cases complete resolution occurs. In a favourable case several weeks may elapse before the disease disappears, while in other cases the cure may be further or even indefinitely delayed. The temperature throughout rarely exceeds 102° , and is often less.

COMPLICATIONS.—The disease is sometimes complicated by other affections, or by aggravations of some of its conditions. Among such occurrences are inflammation and suppuration of the intrinsic joints of the pelvis, erysipelas, limited abscesses of periphlebitic origin, diffuse suppuration of cellular tissue, gangrene of any part or of a varying amount of the entire lower portions of the affected limb. These complications or aggravations cause much danger to life, and in this respect their influence varies according to circumstances. But there are other complications or aggravations which are more often fatal. They may be summed up in the terms 'embolism' and 'pyæmia,' and are the consequences, on the one hand, of detachment of a thrombus in the femoral, or in still larger veins, or, on the other hand, of a more slow breaking up of blood-clots into *débris*, more or less puriform, which enters the circulatory current, and induces a general toxæmia, simple or infective, according to the conditions under which the clots soften.

SEQUELÆ.—The most frequent sequela of phlegmasia dolens is persistent aching of the limb. This is liable to be increased by cold and damp weather, and by derangement of the general health, as well as by exercise. Another is a tendency to oedema of the ankles, more or less persistent. Sometimes the limb remains deficient in muscular power. The atrophy of the muscles may lead to the development of club foot. Rarely, the limb is not only powerless but wasted. And in some very uncommon cases it is the subject of a great hypertrophy of the cellular tissue, simultaneous with muscular wasting; and this cellular hypertrophy may be complicated with more or less extensive and intractable ulceration. Such cases probably result from permanent destruction of large vascular areas.

DIAGNOSIS.—The diagnosis of phlegmasia dolens requires no discussion. The disease can scarcely be confounded with any other if its history is taken into consideration: only it is necessary to remember that oedema with phlebitis or accompanying varicose veins may somewhat resemble it.

TREATMENT.—The treatment of phlegmasia dolens should be both constitutional and local. As

the condition often runs a somewhat asthenic course, in the early stage ammonia in effervescence, with quinine, according to the amount of pyrexia present and the general condition of the patient, and in the later stage iron, are generally useful, with as much sedative as may be indicated by the severity of the pain. Local treatment is very important. The limb is to be kept at rest, either in an extended or flexed position, as may prove most comfortable, and supported on a pillow raised at the foot, with the pressure of the bedclothes kept off by a cradle. Sometimes hot belladonna-fomentations are most comfortable to the patient's feelings, but more frequently wrapping the limb in cotton wool sprinkled with equal parts of belladonna and chloroform liniments, with oil-silk outside, gives the greater relief. When the swelling is subsiding gentle bandaging with a light flannel bandage is very serviceable. If the phlegmasia be associated with septicæmia, its general treatment will of course vary with the general treatment of the toxæmia.

After the acute stage of the disease is past, the sequelæ have to be dealt with. Of these the most frequent are aching, swelling, œdema, and muscular weakness of the limb; and for these the most efficient, but by no means invariably successful, remedies are frictions, bandaging, and faradisation. After all active disease has disappeared, and after danger of dislodging thrombi has passed, the patient may resume the use of the leg. No exact statement can be made of the time at which the danger of embolism is passed. It may prove suddenly fatal as late as thirty-seven days after delivery.

The very rare form of the disease accompanied by extensive cellulitic inflammation of the subcutaneous tissues of the thighs requires energetic stimulant treatment, and free incisions may have to be made.

Persistent local hardness and tenderness, probably periphlebitic, may be treated locally by gentle frictions with a mixture of mercurial and belladonna ointments, but in using frictions of all kinds the danger of dislodging a thrombus is not to be overlooked. Internally, small doses of potassium iodide with quinine or iron are useful adjuvants.

PHLEGMATIC TEMPERAMENT.—See TEMPERAMENT.

PHLEGMON (φλέγω, I burn—as a medical term, glow, am inflamed).—SYNON.: Fr. *Phlegmon*; Ger. *Entzündungsgeschwulst*.—This term may be defined as a circumscribed area of connective tissue in process of acute inflammation. The word is now almost obsolete.

PHLEGMONOUS.—A term applied to extremely acute inflammation of the cellular tissue, spreading widely, and accompanied by great exudation, with brawny hardness, intense redness, heat, and pain. See CELLULITIS.

PHLYCTENULE (φλύκταινα, a blister).—A small vesicle, not exceeding in bulk the diameter of a pea, as in sudamina, miliaria, and herpes. The term is sometimes also used in connection with ophthalmia. See p. 502.

PHOSPHATIC CALCULUS.—DESCRIPTION.

Phosphate-of-lime calculi are sometimes formed in the kidney, but much more frequently phosphatic stones are a secondary deposit on some pre-existing nucleus. They form dense or porous white layers, frequently showing the glistening crystals of the triple phosphate on the surface. Such masses are soluble in acids, insoluble in alkalis or water, friable, and fusible. They develop rapidly, and may reach an enormous size.

TREATMENT.—When of moderate dimensions, phosphatic calculi may be easily removed by lithotripsy; but, as it is often difficult to ensure the removal of every minute particle, and as they are often accompanied by chronic cystitis and deficient expulsive power of the bladder, recurrence is not infrequent, and the ultimate result unfavourable.

WILLIAM CADGE.

PHOSPHATURIA.—A healthy man excretes some 2·3·5 grammes of phosphoric acid in his urine in the course of 24 hours. This is in part derived from food, and is in part a product of metabolism, within the body, of phosphorus-containing substances, such as nuclein and lecithin. In the urine it is in part combined with alkali-metals and in part with calcium and magnesium.

The endogenous phosphate-excretion is subject to marked fluctuations, as also is the relative excretion of phosphates and of nitrogen, but our knowledge of the conditions upon which these depend is not yet sufficient to supply information of conspicuous clinical value. Strictly speaking, the term 'phosphaturia' should only be used to denote an increased excretion of phosphates beyond the normal limits.

However, the name is often incorrectly applied to the passage of urine which is rendered turbid by the precipitation of the earthy phosphates which it contains, the presence of which is thus rendered evident. Such precipitation is merely dependent upon the reaction of the liquid, and affords no evidence of an unduly large output of phosphoric acid. Urine containing such sediments may be alkaline, amphoteric, neutral, or even faintly acid in reaction. The sediment is colourless, amorphous or showing crystalline points, and is readily dissolved by acids. An iridescent film is usually formed upon the surface of the urine.

Amorphous phosphatic sediments consist of the normal phosphates of calcium and magnesium. Calcium Hydrogen Phosphate (CaHPO_4) may also be present in the amorphous deposit, and in amphoteric or faintly acid urines is sometimes deposited in rosettes of wedge-shaped crystals, constituting the so-called stellar-phosphate sediment. Owing to its insolubility in alkaline liquids ammonium-magnesium phosphate (MgNH_4PO_4), usually known as 'triple phosphate,' is apt to be deposited in crystalline form. The crystals are often large enough to be visible to the naked eye, and usually have the form of triangular prisms, with oblique ends—the well-known 'coffin-lid' crystals—but stellate and feathery forms are also met with. The deposition of these crystals is naturally favoured by alkaline fermentation, and the resulting formation of ammonium carbonate, but the requisite ammonia may be derived from the ammonium-salts present in undecomposed urine.

Very rarely crystalline deposits of normal Magnesium Phosphate ($\text{Mg}_3(\text{PO}_4)_2 + 22\text{H}_2\text{O}$) have been observed, consisting of highly refractive rhombic

tables, and in a case of dilated stomach, in which magnesia had been freely administered, Bradshaw recently observed a deposit of long acicular crystals, which he believes to consist of Magnesium-Hydrogen Phosphate ($MgHPO_4$).

CAUSATION.—Deposit of phosphates takes place in many diseases—diseases often of an opposite character, and having no pathological resemblance—for example, in acute cerebral lesions; towards the close of cases of pleurisy, pneumonia, and rheumatic fever; in certain periods of typhoid fever; and in acute mania. But it may be taken as proved that there is no morbid condition, characterised by definite and constantly occurring symptoms, and accompanied by the deposit of phosphates in the urine, which can be entitled to the designation of a ‘diathesis.’ Prout’s description of the phosphatic diathesis is merely that of ammoniacal urine. Golding Bird associated the deposit with symptoms of irritative dyspepsia, hypochondriasis, and temporary exhaustion of the nervous power; symptoms which are not unlike those said to be characteristic of the so-called oxalic-acid diathesis (see p. 1136). Remembering, however, that phosphatic deposit does not necessarily or frequently mean excess, but depends on diminished acidity or on alkalinity of the urine, it will be more profitable to notice this condition.

The urine becomes neutral or alkaline from the presence of either fixed alkali, potash or soda, or of the volatile alkali, ammonia. The continued or frequent presence of alkaline urine from *fixed alkali*, unless due to a vegetarian diet or the free administration of alkalis, denotes disorders, generally characterised by debility, anæmia, and nervous dyspepsia; it may and does occur in the course of many, even acute, diseases; it represents an altered condition of blood and nutrition; but it is not typical of any one malady or diathesis, nor, so far as analytical investigations have yet gone, is there any clear evidence of the truth of the theory that excess or deposit of phosphates and alkaline urine are the result of increased cerebral action or of brain-disease.

Urine rendered alkaline by *carbonate of ammonium* is always accompanied by deposit of both forms of the phosphates. The alkalinity is the result of decomposition of the urea; there is the peculiar ammoniacal odour, reaching sometimes to intense putrid fœtor. This decomposition is due to the presence and action of certain bacteria which cause the urea to split up into carbonate of ammonium and water. These bacteria are probably introduced through the catheter, but the change may occur in those for whom a catheter has never been used, and in them it is supposed that the bacteria may find their way along the mucous membrane of the urethra, or through the medium of the circulation. Ammoniacal urine is always indicative of lowered vitality, either from age or disease, or spinal injury; it points to no altered condition of blood or constitution, but is the result of local disease. The phosphates which are so freely thrown down are the triple phosphate and the amorphous phosphate of calcium; they are readily deposited on any pre-existing nucleus, whether it be a stone, a clot of blood, a roughened ulcerated portion of bladder, or any foreign body; but without this pre-existing nucleus it but rarely, if ever, happens that such concretions form.

TREATMENT.—As there is no real phosphatic diathesis requiring special management, it follows

that the treatment should consist in removing the cause of the alkalinity of the urine from *fixed alkali*. The two most common causes are dyspepsia and nervous and general debility. In those cases of chronic vomiting and irritable dyspepsia in which the urine loses and recovers its acidity several times daily, no special remedies addressed to the state of the urine can be of any avail. The mineral acids have long been relied on for restoring the natural acidity of alkaline urine; it seems certain, however, that they have no very marked influence in this respect, but simply act beneficially by their indirect tonic effect on the system. Phosphoric and benzoic acids may slightly add to the acidity of the urine, and opium and belladonna in certain conditions of nervous irritability are known to have the same effect; but, speaking generally, the mineral, vegetable, and acid tonics are required in almost all cases, and with them the usual adjuncts, namely, good air and exercise; the cold sea-water bath; a well-selected generous diet, largely composed of animal food; and relief from anxiety or over-work.

For alkalinity and phosphatic deposit depending on ammoniacal decomposition, it must be remembered that in this state the urine is almost always secreted acid. The local disease which causes it must, if possible, be remedied: a stone should be removed; an atonic bladder emptied at stated intervals by the catheter, and washed out with antiseptics, if necessary. In certain cases, as in the cystitis of enteric fever, the administration of urotropine has very beneficial effects. The strength is always to be upheld by rest, good diet, and tonics.

A. E. GARROD.

PHOSPHORUS-MAKERS.—See OCCUPATION-DISEASES.

PHOSPHORUS, Poisoning by.—SYNON.: Fr. *Intoxication Phosphorée*; Ger. *Phosphorvergiftung*.

Phosphorus acts as a poison only when in the form of yellow, common, or soluble phosphorus; in the allotropic form of red or insoluble phosphorus it is generally thought to be inert, but this is doubtful. Poisoning by phosphorus may be (1) *acute* or (2) *chronic*.

On the Continent phosphorus, in the form of the tips of lucifer matches, is frequently used for suicidal purposes. Acute poisoning by phosphorus is also not uncommon in this country. In England phosphorus is most commonly taken in the form of ‘rat paste’ or ‘phosphorus paste,’ a vermin-destroyer composed of butter or other fats and phosphorus, coloured with Prussian blue. Chronic phosphorus-poisoning from the inhalation of phosphorus-vapours has long been recognised.

ANATOMICAL CHARACTERS.—These are well-marked, and consist of extreme fatty degeneration of the liver, and also of the gastric mucous membrane, kidneys, and cardiac muscular fibre. The liver is also greatly enlarged and white; and the organ frequently takes fire on the mere application of a spirit-lamp flame. On microscopical examination the organs affected are seen to be infiltrated with granular fatty matter, soluble in ether; the gastric tubuli are also filled with granular fat; and the striated muscular fibre has more or less completely lost its normal appearance, and been converted into a similar granular material.

SYMPTOMS.—1. *Acute Phosphorus-Poisoning.*—When a phosphorus mixture is swallowed a disagreeable taste is perceived, which is occasionally followed by a burning sensation in the throat, gullet, and stomach, and speedy vomiting. But these signs of the local action of the poison may be either absent or altogether inconsiderable. At any rate, as a rule, these and the diarrhoea and colicky pains described by some writers soon pass off, leaving the patient apparently nearly well; though a careful examination may reveal a small, feeble pulse, and when the patient is questioned, the existence of obscure wandering pains may be admitted. In the course of a few days—usually two, three, four, or five—the patient becomes listless, dull, and slightly jaundiced. There is much headache and sleeplessness, together with a general febrile condition, gradually passing into a ‘typhoid’ state; increasing jaundice; scanty, high-coloured, bile-stained urine; and a quick and very feeble pulse. Muttering delirium supervenes; there may be violent vomiting of yellow, biliary mucus; and the patient gradually sinks, and dies after a day or two, or perhaps three or more, of acute disease, and usually within a week of the administration of the poison. Death may occur, however, at any period, from one or two to eight or ten days, after a fatal dose of phosphorus, which may, perhaps, be taken as half a grain for an adult person.

Variations from the above course of symptoms may be noted. In one class of cases the symptoms betoken a predominance of nervous action. Thus there are cramps and pains in the limbs, great prostration and faintness, convulsions, and, finally, coma. In another class, occasionally observed, hæmorrhagic symptoms are prominent, such as bloody vomits and hæmorrhagic diarrhoea. As an early symptom a phosphorescent condition of the vomited matters, and, more rarely, of the urine, may be noted; and in nearly all cases a peculiar garlicky odour of the breath is perceptible. The phosphorescence or luminosity of the rejected matters is of course best seen in the dark. If the phosphorescent condition of the vomit exist, this permits of no mistake in the diagnosis; but if this condition be absent, the garlicky odour of the breath, and an enlarged condition of the liver, greatly aid in the diagnosis.

2. *Chronic Phosphorus-Poisoning.*—Chronic phosphorus-poisoning consists in poisoning by phosphorus-vapours. Workers in common or yellow phosphorus exhibit a singular form of disease from which workers in red or amorphous phosphorus are exempt. This consists in caries of the teeth and necrosis of the lower jaw. See **TEETH**, Diseases of; and p. 1112.

PROGNOSIS.—This is in all cases very unfavourable, and no general rules can be laid down as to the issue.

TREATMENT.—We know but little respecting this matter. Good results appear to be obtained from the administration of an emetic of copper sulphate, followed by a magma of magnesia, and the use of mucilaginous drinks. The best results, however, have followed the administration of oil of turpentine, which some regard as a specific antidote to phosphorus. It may be given in doses of 10 to 20 minims, frequently repeated. Or, dilute solution of hydrogen peroxide or of potassium permanganate may be administered freely.

The chronic form of the disease, which has led

to horrible suffering and deformity, may be prevented by the use of red instead of yellow phosphorus in the making of matches. The use of respirators, and the impregnation of the atmosphere with the vapour of oil of turpentine, are also preventive measures of great service.

THOMAS STEVENSON.

PHOSSY JAW.—See p. 1112.

PHOTOPHOBIA (φῶς, light; and φόβος, fear). Dread or intolerance of light; a symptom, more or less constant, of most forms of inflammation of the eye. In its most pronounced character it occurs in what is called ‘strumous ophthalmia,’ or phlyctenular keratitis. It is, however, present in all forms of inflammation and ulceration of the cornea, in iritis and cyclitis, and more rarely in choroiditis and retinitis. It is also often met with in many diseases of the nervous system, in cerebral irritation, meningitis, encephalitis, &c., and in many pyrexial states. As an ophthalmic symptom, it may occur in eyes perfectly blind, and is probably due to the irritation of the ciliary nerves by light. See **EYE**, AND ITS APPENDAGES, Diseases of.

PHOTOPSÍA (φῶς, light; and ὄψις, vision).—The subjective sensation of flashes of light, or luminous spectra, due to an abnormal state of some part of the special nervous apparatus of the visual sense. It is a modification of the special sensibility, and, like photophobia, may occur in blind eyes. See **VISION**, Disorders of.

PHRENIC NERVE, Diseases of.—**SYNON.** : Fr. *Maladies du Nerf Phrénique*; Ger. *Krankheiten des Nerven Phrenicus*.—The phrenic nerve, arising from the third and fourth cervical roots, is the motor nerve for the diaphragm. Morbid states of the nerve, its roots and centre, are manifested by inaction or over-action of the diaphragm, its paralysis and spasm.

1. **Paralysis.**—**ÆTIOLOGY.**—Paralysis of the phrenic nerve, that is, of the diaphragm, is rarely due to disease of the nerve-trunk. Its common cause is disease at the origin of the phrenic—the anterior grey matter of the spinal cord at the level of the third and fourth cervical nerves. It is often met with as part of acute or chronic spinal muscular atrophy. But the nerve itself has sometimes suffered, with others, in multiple neuritis. In a few cases the paralysis has been apparently due to cold, supposed to have caused a rheumatic neuritis, and rarely to compression in the neck by deep-seated morbid growths.

ANATOMICAL CHARACTERS.—Degeneration of the trunk of the nerve, wasting of the nerve-fibres, and increase of connective tissue have been found in cases of disease of the spinal cord; and in multiple neuritis there are acute degenerative changes in the nerve-fibres. Of the anatomical changes due to other causes nothing is positively known. Degeneration of the muscular fibres of the diaphragm is found as a consequence of disease of the nerve.

SYMPTOMS.—The evidence of paralysis of the phrenic is inaction of the diaphragm. When one nerve only is diseased there is imperfect action on one side, and this may be conspicuous or indistinct. When both nerves are affected, as is commonly the case in central disease, there is an entire absence of the normal protrusion of the abdominal wall during inspiration; there may even be a recession of the upper part of the abdomen, from the movement of

the lower ribs, and a bulging during expiration in the same situation. In ordinary breathing the respiratory action is not quickened by paralysis of the diaphragm, but if any exertion is made the respirations become more frequent, and the extraordinary muscles of respiration are thrown into action. All spasmodic respiratory actions—sneezing, coughing—are performed with less energy. Little inconvenience is experienced unless bronchitis comes on, and then the lessened respiratory power may place the patient in a condition of danger, which is especially great if, as is often the case, the central cause of the palsy has also weakened the intercostal muscles.

The phrenic nerve is accessible to direct stimulation in the root of the neck, and when it is paralysed its irritability is usually lost, and the diaphragm can no longer be made to contract. In rare cases, however, the nerve-trunk retains its excitability.

DIAGNOSIS.—The diagnosis of paralysis of the diaphragm is not always so simple a matter as might be supposed. Its action should be looked for not only in deep breathing, but in ordinary respiration. Many persons if told to 'take a deep breath' do not put the diaphragm into action at all. In forced breathing the chief extra action takes place in the upper part of the chest, to which most of the muscles of extraordinary respiration are attached. It is probable that the centres for normal and extraordinary breathing are functionally not identical, and that the diaphragm is chiefly represented in the former, so that it does not necessarily act in deep breathing. There is a mechanical reason for this. In the extreme action of the intercostal muscles the thorax is widened to such a degree that the diaphragm becomes less curved by the movement outwards and elevation of its points of attachment, so that its contraction does not effect much additional enlargement of the capacity of the thorax. Hence, in many persons, without any paralysis of the diaphragm, if a deep inspiration is taken, the epigastrium does not advance; it may even recede, in consequence of this movement of the lower ribs. This is especially the case in women, in whom breathing is always less diaphragmatic than it is in men. In them, too, conscious attention to the act of breathing is apt to arrest the action of the diaphragm. The tendency of voluntary breathing is to be costal rather than diaphragmatic, no doubt because the centre for extraordinary breathing, which is chiefly voluntary, is brought partially into action. In a woman under the writer's care, paralysis of the diaphragm was suspected, and during two separate and prolonged examinations not the slightest action could be observed. On a third examination, however, more normal conditions were obtained, and the action of the diaphragm was natural. This is the condition which has been termed 'hysterical paralysis of the diaphragm.'

It must not be forgotten that immobility of the diaphragm may result from other causes than paralysis of the phrenic nerve. In diaphragmatic pleurisy and acute peritonitis, its movement is lessened by a reflex inhibitory effect of the pain. In emphysema of the lungs, in which the thorax is greatly widened, the contraction of the diaphragm produces less effect than in health.

On the other hand, when the diaphragm is really paralysed, a doubt may arise as to whether it moves or not. This is due to the circumstance that the movement of the lower ribs may drag forward the

abdominal parietes close to them, and so the protrusion due to descent of the diaphragm may be simulated. This is especially the case when the abdomen is collapsed, so that when the patient is recumbent its level is considerably below that of the ensiform cartilage. This movement may be distinguished from that due to the descent of the diaphragm by a little care; the movement is confined to the part near the thorax, and there is not the general movement of the abdominal viscera and parietes which results from the contraction of the diaphragm.

PROGNOSIS.—The prognosis of paralysis of the diaphragm is favourable in the rare instances which are due to exposure to cold, and in multiple neuritis, if the patient lives. This nerve, however, is seldom paralysed, except in severe cases of polyn neuritis, in which the prognosis is grave; the prospect of recovery is rather less favourable in lead-poisoning. It is also unfavourable when the diaphragm suffers as part of progressive spinal muscular atrophy. When there is acute spinal muscular atrophy (anterior polio-myelitis), the prognosis will depend on the indication afforded by other symptoms of the position of the chief disease, as to whether the region from which the phrenic nerve arises is gravely or slightly damaged. When the paralysis arises from compression, the prognosis depends on the nature and cause of the pressure.

TREATMENT.—The treatment of the paralysis, which is part of spinal amyotrophy, whatever the nature of the morbid process, is that of the central disease. In all cases causal indications must be met. When it is due to cold, sinapisms should be applied over the part of the phrenic nerve which seems, from any attendant pain, to be chiefly affected. If the nerve has not lost its irritability, it may be faradised systematically. The two points to which the rheophores should be applied are (1) in the neck, just above the scaleni, and (2) near the diaphragm. A strong current has to be used.

2. **Spasm.**—Spasm of the diaphragm occurs chiefly in the form of hiccough, and as part of the respiratory spasm in hydrophobia, and does not need further description. See DIAPHRAGM, Diseases of; HICCOUGH; and HYDROPHOBIA.

W. R. GOWERS.

PHTHIRIASIS (*φθελρ*, a louse). — **SYNON.** : Pediculosis; Fr. *Phthiriase*; Ger. *Läuseucht*.

DESCRIPTION.—There are three varieties of phthiriasis, corresponding to the three species of pediculi that infest the human body. See PEDICULUS.

1. **Phthiriasis capitis.**—Phthiriasis affecting the head is met with chiefly in children. The eruption is an artificial pustular eczema, due to the irritation of the insect, the scratching of the sufferer, and the subsequent growth of pyogenic cocci thus introduced. The superficial lymphatic glands at the back of the neck often become enlarged from secondary infection.

2. **Phthiriasis corporis.**—Phthiriasis of the body is confined to the parts covered by the clothes, and is most developed on the back. It is especially met with in the old and feeble. The lesions of the skin consist of small excoriations and scattered papules, the tops of which are seen to be torn and bleeding from the scratching of the sufferer. These bleeding papules give to the eruption its characteristic appearance. In chronic cases the general colour of the skin is darkened from an excessive deposit of pigment.

3. **Phthiriasis pubis.**—This variety of phthiriasis differs little from that of the body, except that it is limited to the regions infested by the crab-louse.

All three varieties of the disease are attended by intolerable itching.

TREATMENT.—In *Phthiriasis Capitis* the parasites may be destroyed by means of an ointment composed of equal parts of mercury oleate (5 per cent.) and ether. The hair must be well and diligently combed to free it from nits. The rubbing in of petroleum is a favourite application for this purpose. In the case of a child the head should be shaved.

Phthiriasis Corporis is easily cured by means of an ointment containing one part of the oil of stavesacre and seven parts of lard; or the white-precipitate ointment may be safely used. The underclothing must be baked in a disinfecting oven. A hot bath, with free use of carbolie soap, facilitates the removal of any ova adherent to the hair.

In *Phthiriasis Pubis* oleate of mercury (5 per cent.) mixed with ether in proportion of 3 to 1, or ammoniated mercury ointment will effect a rapid cure.

ROBERT LIVEING.

PHTHIRIUM INGUINALE (φθείρ, a louse).—One of the synonyms of *Pediculus pubis*, the crab-louse. See *PEDICULUS*; and *PHTHIRIASIS*.

PHTHISIS (φθίσις, I waste).—**SYNON.** : Consumption; Lung-Tuberculosis; Fr. *Phthisie*; Ger. *Lungenschwindsucht*.

DEFINITION.—Phthisis, or consumption, is the term used to designate a disease characterised by progressive wasting of the body; persistent cough, with expectoration of opaque matter and sometimes of blood; loss of colour and strength; shortness of breath; hectic fever, night-sweats, and diarrhoea; these symptoms being associated with certain well-marked pathological changes in the lungs, namely, the formation of consolidations in a granular or diffuse form, associated with the presence and irritating influence of an organism, the *Bacillus tuberculosis*; these undergoing either caseation or disintegration, leaving behind excavations in the lung-tissue, or, becoming indurated and shrinking, causing contraction of the affected organ.

ÆTIOLOGY AND MORBID ANATOMY.—In the article on *TUBERCULOSIS* will be found a full account of the various predisposing conditions of phthisis. See *TUBERCULOSIS* and *PNEUMOCONIOSES*.

PATHOLOGY.—The first effect of the entry of the tubercle-bacillus into the alveoli would be epithelial proliferation, and possibly, from penetration of the capillaries, exudation of fibrin, and leucocytes. If the bacilli enter by the mucous membrane of the bronchi typical tubercles will be formed. If they are very numerous, or the irritation they set up be very considerable, the alveoli may be stuffed with exudation and epithelial proliferations, which would rapidly caseate. If, however, the irritation be less, the process is slower, more new cells are formed, and a powerful attempt of the organ at self-protection is made (see *PHAGOCYTOSIS*). These cells may in turn perish under the attack of the invader, or be converted into fibroid tissue, and thus resist further advance by encapsulation. The interalveolar lymphoid growth may be the result of bacillary irritation of the alveolar wall; but, being devoid of blood-vessels, it soon undergoes caseation through the action of the bacilli. The histological element, the growth of the interlobular tissue, though it may

be due to bacillary irritation, has a distinctly limiting influence on the advance of the organism, and no bacilli have hitherto been found in this tissue. Tubercle-bacilli are found invariably in freshly formed tubercle, but in grey or milky of some date they are often absent, owing to the tubercle having undergone fibrosis. They are present in white and yellow granulations, and in recently formed caseous masses, but not in the other pathological elements, which, though associated with tubercle, are mainly of inflammatory origin.

The process of softening is due partly to overcrowding of the corpuscular products and partly to a chemical process, arising, according to Watson Cheyne, from bacillary action.

When cavities have formed, bacilli swarm on their walls and in their contents, and the more rapidly they are formed the larger the number of bacilli present.

It is obvious that, whatever part the bacillus plays in the causation of phthisis, the condition of the individual attacked, and his constitutional powers of resistance, are quite as important, as on these depend the whole question of vulnerability. It is probable that in most cases of consumption the bacilli reach the lungs through inhalation; but why, out of a number of persons placed under similar conditions, apparently necessitating the inhalation of tubercle-bacilli, in only a few they increase and multiply, is hard to explain, but renders the existence of a predisposing cause necessary. Koch believes the denudation of the bronchial mucous membrane after measles renders the lungs liable to bacillary attack; and that, similarly, denudation of the intestinal mucous membrane by the shedding of its epithelium from any cause offers the chance of infecting this part by the swallowing of sputum laden with bacilli. Moreover, chronic pleurisy or any cause which tends to cripple the movements of the lung, or to prevent the escape of its secretions, will predispose by forming aggregations of epithelial cells, which are the haunt of tubercle-bacilli.

The spread of bacilli in the lung may proceed (1) by continuity, through the alveolar wall, the epithelium having been destroyed; (2) by re-inhalation of bacilli-laden sputum, especially if expectoration be difficult—the secretion, being raised by coughing to a point where two or more bronchi join, is drawn by deep inspiration into a fresh set of alveoli; (3) through the lymphatics, as is often seen in the stellate arrangement of grey tubercle round a cavity or caseous centre; (4) through the arteries and veins, the entry of the bacilli into these having been demonstrated by several observers. This is the channel of infection in acute tuberculosis.

With reference to the order in which the various portions of the lungs are involved in phthisis, the posterior apex (Fowler) is first attacked, and the lesions spread downwards along the anterior aspect of the upper lobes; the posterior upper border of the lower lobe is next infected, and tuberculisation spreads again forwards along its upper edge. The posterior region seems to be attacked altogether earlier than the anterior; excavation is commonest and earliest (Ewart) at the apex, next in the dorso-axillary and mammary regions, and later and less common at the base. Cavities in the dorso-axillary and mammary regions are invariably secondary, and generally the result of re-infection of the lung from secretion from cavities.

CLINICAL FEATURES.—I. Early Lesions.—

Symptoms.—The symptoms of pulmonary phthisis in the first stage may be thus summarised: Cough, becoming more persistent; mucous expectoration; loss of colour and strength; emaciation; night-sweats; sometimes loss of hair; pulse somewhat quickened, though this is not invariable; and a temperature rising above the normal in the afternoon, and sinking below it in the morning. Peter has noted in many cases a rise in temperature on the affected side during this stage; and with regard to the general temperature of the body, though slight pyrexia is often present, tubercle-formation is quite possible without any rise of temperature, or may even be marked by a depression. Pain in the upper parts of the chest is occasionally present (*see PAIN IN VISCERAL DISEASE*); and the number of respirations is generally increased, though this depends on the extent of lung involved and the degree of anæmia present. Some hold that dyspnoea is an early symptom and precedes all others, but the writer has found that as a rule patients do not notice their breath to be short until their lungs are seriously involved. Disturbance of the digestive powers, and considerable irritability of the intestinal mucous membrane, with a red line on the gums, are noticeable in some cases, though chiefly in the acute forms. The tongue becomes white, the bowels torpid, and the urine scanty. The most constant of the above symptoms are the persistent cough, with mucous expectoration, and the progressive emaciation; and in many cases these are the only symptoms discoverable.

Physical signs.—The physical signs, after the first stage, depend to a great extent (1) on the number and aggregation of the miliary tubercles; (2) on the amount of consolidation to which they have given rise; and (3) on the irritation which their formation causes in the lung.

As a rule, tubercle-formation commences at the apex of one lung, and is detected by the presence of certain physical signs in the supra-scapular, supra-clavicular, or sub-clavicular regions, the signs extending downwards at a later date. The signs vary much in particular cases, but consist at the first in an impairment of the ordinary respiratory murmur by a species of crepitation, differing from the pneumonic crepitation chiefly in its more scattered character, in its being audible with both inspiration and expiration, and in its crumpling nature. At first these crepitations may be audible only on deep inspiration immediately after coughing, which should always be practised during auscultation. Many authors, however, maintain that an earlier sign is the 'wavy' breathing or '*respiration saccadée*' of the French. A noteworthy feature is increased loudness of the expiratory murmur. Accompanying these is increased vocal resonance and bronchophony, more distinct conduction of the cardiac sounds, and deficient resonance on percussion in one of the above-mentioned regions. When a certain definite amount of consolidation has taken place some impairment of the mobility of one side of the chest may be noticed: this is to be detected under the clavicle, where, if any adhesion of the pleura exists, there may be some flattening. Another significant sign is the dry friction-sound, audible generally in the supra-scapular and scapular regions, and indicating limited pleurisy. The dulness usually appears first above the scapula, next over the sternal end of the clavicle, and gradually

extends downwards, being limited generally for a considerable period by the lower border of the third rib.

A careful comparison must be made between the two sides of the chest, and often between different portions of the same side, as otherwise the slighter shades of dulness, and the minor differences in the respiration-sounds, which characterise the presence of tubercle in the lung, will escape notice.

When the crepitation and the wheezing—which may be considered as indicative of irritation in the pulmonary tissue, caused by tuberculosis—have subsided, loud bronchophony, prolonged expiration, and certain varieties of tubular sound, show condensation of the lung-tissue around the neighbouring bronchi; and a certain amount of dulness is to be detected.

2. Softening and Excavation.—*Symptoms.*

The symptoms which accompany the softening of tubercular masses and their subsequent excavation are by no means uniform. Many authors associate this stage with marked signs of pyrexia, with copious night-sweats, and increase of cough and emaciation; but this is not always the case, for, according to the writer's experience, the process may go on with even subnormal temperatures, and with gain of weight; but as extension of the disease often accompanies the softening process, some of the above symptoms, which have been assigned to softening, may be due to the fresh infection and pneumonia caused by it. The symptoms which should be most depended upon for the detection of softening are increase of cough and expectoration of a yellow colour, occasionally streaked with blood. If the expectoration be carefully examined, elastic tissue, tubercle-bacilli and other organisms may be found. *See BACTERIA; SPUTUM, Examination of; and TUBERCULOSIS.*

Physical Signs.—The signs which these changes give rise to are often obscure. The percussion-sounds vary: sometimes there is an increase of dulness, possibly due to pneumonia of adjacent lobules; at other times, hyper-resonance, as if air had taken the place of the expectorated masses. In all these cases much depends upon the situation of the lesion. The formation of a cavity deep in the lung, and far from the chest-walls, may take place without being detected (except by the expectation); whereas the formation of a similar cavity on the surface gives rise to unequivocal signs. Auscultation reveals—where formerly bronchophony and fine crepitus existed—crepitation of a very coarse character, commencing with a *click* sound, and after a while developing into a *croak*. When this last note has been reached, loud tubular sounds become audible on coughing, and we soon get the sounds characteristic of a cavity. The great distinguishing features of these moist sounds of softening are their variety, their short duration, and their concentration over one small portion of the lung. In phthisis, crepitation much more commonly signifies tubercle-formation or pneumonia than it does softening of already formed tubercular masses. The formation of a cavity is generally followed by regular morning expectoration, usually opaque, and nummular in form, and in the majority of cases, unless interfered with by treatment, by the usual train of consumptive symptoms, if these have not already appeared. These are—night-sweats, slightly elevated temperature in the afternoon, and rapid loss of flesh, strength, and colour. The drawn look of the face, the hectic spot on the cheek,

with great rapidity, owing probably to the pyrexia and fitfulness of the appetite.

6. Hæmorrhagic Phthisis.—This name is intended to designate, not phthisis arising from the results of hæmoptysis (*phthisis ab hæmoptoe*—Niemeyer), but a form recognised by C. J. B. Williams, Peacock, Hughes Bennett, and the writer, in which large and repeated hæmorrhage is the principal feature, associated with a small amount of detectable disease. It is more common among men than women, in the proportion of five to one; and the period of attack is later than in the ordinary forms, possibly owing to the element of heredity being generally absent. The patient may have had signs of failing health before the hæmoptysis, but often he is apparently in good health, when he is suddenly attacked with profuse hæmoptysis, the blood being florid, the hæmorrhage sometimes lasting many days, and always causing a reduction in flesh and strength. Cough and expectoration follow, yet examination of the chest only indicates slight signs, and sometimes none at all. When present they are to be found in the supra- or inter-scapular regions, or below the clavicle. The patient improves, and often entirely loses his cough before the recurrence of the hæmorrhage, which may not take place for days, weeks, months, or even years. If the attacks recur often, the cough becomes persistent; the expectoration, when not sanguinolent, is mucopurulent; wasting and night-sweats appear; and the physical signs now show unmistakable consolidation, which goes on to softening and excavation. In most cases the disease does not extend beyond consolidation, and large quantities of blood are expectorated without fatal results, the patients recovering in the intervals, and sometimes living to a considerable age. Peacock stated that in most instances some more or less exciting cause of a depressing character is to be detected, in the form of syphilis, cold, dysentery, bodily strain, exertion of voice; but the observer will often fail to find one. The exact pathology of this form of phthisis is uncertain, because few of the patients die in the early stage; but it is probable that the hæmorrhage is produced by the erosion of the pulmonary vessels by bacillary invasion, masses of tubercle-bacilli having been shown to be present in the walls of both arteries and veins; and in hæmorrhagic phthisis it is probable that the larger vessels are thus attacked.

DIAGNOSIS.—Phthisis is distinguished from other chest-affections by the presence of tubercle-bacilli in the sputum and by the evidence of physical signs. The evidences of consolidation separate it from bronchitis; while the tendency of the signs to become localised in the apices of the lungs, their special characters, and the combination of consumptive symptoms, distinguish it generally though not invariably from pneumonia due to other causes.

Of the various forms of phthisis, the most difficult to diagnose from other diseases is acute milary tuberculosis, which at its onset is sometimes mistaken for acute bronchitis, from the fine *râles* and rhonchi accompanying the milary formation. It has also been confounded with enteric fever, from the high pyrexia, the depression of the patient, and the occasional diarrhoea accompanying it; but in both cases the rapidly advancing symptoms, and the steadily progressing physical signs, such as increased and scattered crepitation, if frequent careful

examinations be made, ought to leave us in no doubt as to the nature of the case.

The diagnosis between acute phthisis and croupous pneumonia is not easy at the onset of these complaints, the physical signs not always sufficing for this purpose. In a short time, however, the detection of tubercle-bacilli, and later of lung-tissue in the sputum, and the rapid wasting, make matters quite certain.

The diagnosis of chronic tubercular phthisis from anæmia and chlorosis, sometimes confused with it on account of the amenorrhœa often common to both, is made by the physical signs; by the different kinds of pallor in the two diseases; and, lastly, in chlorosis, by the absence of wasting. The diagnosis of excavation in phthisis from bronchiectasis is by no means easy, as the position of the cavernous sounds is not always sufficient to determine the nature of the lesion. Dilated bronchi are found in the subclavicular and interscapular regions, and where ulceration is proceeding in bronchiectasis lung-tissue may be detected in the sputum; but the presence of tubercle-bacilli at once settles the question in lesions of phthisis, while the convulsive character of the cough, and the fœtid expectoration, abundant, but mixed largely with air, generally enable us to decide in favour of dilated bronchi. The diagnosis from cancer, especially from sarcoma of the lung, depends partly on the symptoms, and partly on the physical signs which, in the case of sarcoma, present larger areas of dulness and generally of a more intense kind, and the remarkable shutting off of all breath- and voice-sound, which cases of lung-cancer present. See MEDIASTINUM, Diseases of.

DURATION AND PROGNOSIS.—Early detection of the disease, and improved treatment, have worked a great revolution in our ideas as to the *duration* of phthisis.

The statistics of C. J. B. Williams and the writer, founded on 1,000 cases among the upper classes, give an average duration in 198 deaths of 7 years 8·72 months; and in 802 living of 8 years 2 months. The fact of these patients having all been one year and upwards under observation necessarily excludes some of the acute cases; but with this limitation these figures, striking though they be, may be taken as a correct average for the duration of the disease among the upper classes under modern treatment, especially as 72 per cent. of the living had recovered sufficiently to pursue their usual avocations, and many among them had already lived upwards of twenty years since their first attack. The duration of the disease is found to be considerably influenced by age; for it is longer in proportion as the age of attack is later, this retarding influence being more conspicuous among males than females. Females are attacked earlier, and the disease in them runs a shorter course by nearly two years than among males.

Of the varieties of phthisis, acute tuberculosis is the most rapid in its course, generally terminating in a few weeks, or occasionally in a few days. Acute phthisis has hardly a less rapid course, though it may occasionally be retarded, the disease becoming chronic, and the patient surviving for many years. Catarrhal phthisis has an average duration somewhat below the average of eight years of ordinary phthisis. Fibroid phthisis, on the other hand, exceeds the ordinary duration by nearly two years. Hæmorrhagic and scrofulous phthisis are both of

long duration. These calculations are based on statistics of patients of the upper classes treated according to the best medical and hygienic treatment known; but if hospital cases are reckoned, the average duration of phthisis generally, and of its various forms, must be held to be much lower than the above estimate.

The prognosis in phthisis depends chiefly on the extent to which the system is infected, and especially whether or not other organs are the seats of tubercle. Cases of acute tuberculosis resemble closely those of pyæmia in their symptoms and fatal course, and only differ in the nature of the pathological products. Similar single-cavity cases, where the disease is strictly limited, bear a strong resemblance to chronic abscesses, which go on discharging for long periods, without materially curtailing the life of the patient. The future, therefore, of the patient depends to a great extent on whether the disease may be considered local or general, though of course we admit in both instances a constitutional predisposition, possibly of different degrees of intensity. Where the infection is rapid and complete, as in acute tuberculosis and most instances of scrofulous pneumonia, the prognosis is most unfavourable. Where, again, the disease is limited to one lung, and associated with similar processes in the joints, as in scrofulous phthisis, which act as diverticula to the central disease, the prognosis becomes far more hopeful, and the individual may last on for many years.

The prognosis in hæmorrhagic phthisis, where the pulmonary mischief is small and limited to the root of the lungs, is favourable, excepting of course the accident of death during an attack of hæmorrhage. The most favourable prognosis of phthisis must be retained for cases of inflammatory origin, for here the disease often remains limited for considerable periods of time, and the patient may live on, almost unconscious of it, to the natural term of life. If, however, the fibroid element be largely produced, a new danger arises from the obstruction to the circulation caused by the contraction of the lungs, which may be followed by dilatation of the heart, dropsy, and death.

The influence of *heredity* on prognosis lies in rendering the individual less resistant to the attack of the tubercle-bacillus; consequently he is attacked at an earlier age. Maternal inheritance is worse for the children of both sexes than paternal, for while the father transmits with the disease a certain degree of resisting power, the mother transmits with the disease the lack of resisting power which is the characteristic of her sex. The influence of *stage* must be duly taken into account, for statistics show a far more favourable prospect for mere consolidation than when a cavity is formed, and this is obvious from the increase of danger arising from two sources, namely, from purulent infection and pulmonary aneurysms. The use of mountain climates is believed to have largely improved the prognosis of tubercular consolidation, and to have increased the percentage of recoveries in this stage.

The grounds for an unfavourable prognosis are: (1) rapid extension of disease or of lung-excavation; (2) persistent afternoon pyrexia; (3) symptoms of great irritability of the gastro-intestinal tract, red tongue, diarrhoea, pain in the abdomen; (4) great wasting with, or without, pyrexia, combined with a good appetite; (5) strong hereditary predisposition; (6) the presence of albumen in the urine, with or

without some form of dropsy; (7) marked dyspnoea, especially if not warranted by the condition of the lungs; (8) the existence of considerable excavation in both lungs and the occurrence of pneumothorax.

TREATMENT.—The treatment of phthisis may be considered under four heads: (1) *treatment by inoculation and by anti-tubercular serum*; (2) *medicinal*; (3) *dietetic and hygienic*; and (4) *climatic*.

1. *Inoculation.*—In 1890 Koch introduced the treatment of phthisis by hypodermic injection of *tuberculin*, a glycerine-extract of a pure cultivation of tubercle-bacilli, in which the parasites had been killed; and maintained that early-stage cases could be cured after four to six weeks of this treatment. Subsequent experience from all parts of the world did not confirm this statement, but demonstrated that, while tuberculin had a strong affinity for tuberculous lesions in various organs of the body and gave rise to characteristic constitutional reactions, it caused breaking down of the tubercular masses, and of the lung-tissue in their immediate neighbourhood, fresh eruption of tubercle, and extension of old cavities, the sputum containing an increased number of tubercle-bacilli, and a considerable amount of lung-tissue. Virchow found in the necropsies of patients treated by this method various kinds of pneumonia, including what he termed 'injection catarrhal pneumonia,' and in one case tubercular meningitis, which he attributed to this treatment. By treating it with platinum chloride, Klebs extracted from tuberculin an albumose called tuberculocidin, along with certain alkaloids, and attributed to it the power of arresting tubercle; and these and other modifications of tuberculin have been tried in the treatment of phthisis, without any success. Koch introduced later on two new preparations, viz. *Tuberculin O* and *Tuberculin T R*, prepared by pounding in a mortar dried cultures of the tubercle-bacillus, adding distilled water, and then centrifugalising in a powerful machine. The clear fluid at the top is used for inoculation as *O Tuberculin*, and the residue again treated with water as *T R Tuberculin*. Both preparations are preserved by the addition of 20 per cent. of glycerine before injection. The experience of these preparations has not been altogether favourable. Maragliano, the writer, and others have treated tuberculous patients with anti-tubercular serum, produced by inoculating immune animals, such as horses, goats, and asses, with tuberculin and then withdrawing serum and injecting it into the patients, but the results have never shown any considerable amount of success.

2. *Medicine.*—The medicinal treatment must be directed to four objects: firstly, antipthithical, to raise the standard of nutrition and to fortify the individual against the bacillary invasion; secondly, antiseptic, to promote the destruction and elimination of the *Bacillus tuberculosis*; thirdly, to reduce and allay the local inflammations and congestions which accompany and considerably complicate the tubercular changes; and, fourthly, to relieve the various urgent symptoms. The first object is carried out by tonics, such as iron, quinine, arsenic, the mineral acids, and, above all, cod-liver oil, which has been shown to be the most effective agent of all in improving nutrition and rendering the individual less liable to bacillary attack. Some precautions are, however, necessary to ensure its being tolerated for long periods. The pale oil should be preferred, and ordered in doses of from 5j to 3ss shortly before or after meals. The best

and lips, gastric disturbance and diarrhoea, and occasional delirium, the symptoms closely resembling those of enteric fever, for which the disease is often at first mistaken. Cough and slight expectoration come on; fine crepitation and bronchial rhonchus take the place of the ordinary vesicular sounds; and occasionally some dullness is detected over the posterior regions of the chest. The patient wastes rapidly; the breathing becomes more and more embarrassed; the sputum rusty; the crepitation more general and louder. Later on, the symptoms of collapse appear—the pulse becomes more rapid and feeble, the aspect ghastly or livid, cold perspirations appear; and death occurs within a few weeks from the date of the first onset. Or the symptoms may be more cerebral in character, denoting that the meninges are the seat of miliary tubercle. The patient complains of pain in the head, vomiting, and intolerance of light; begins to mutter and to give wrong answers; and then has marked delirium. The aspect is heavy and confused; hyperæsthesia of skin appears (Empis); and double vision, though squinting is not always noticeable. Granulations can often be detected with the ophthalmoscope in the fundus oculi. Twitchings of the muscles of the extremities and sometimes of the face occur, followed by convulsions, and by paralysis of the sphincters. Dilatation of the pupils and other signs of effusion supervene, and the patient dies comatose. In this variety, as a rule, the temperature remains continuously high (between 100° and 102° F.), but in some instances it may be observed to rise above 100° F. for the last ten days of the patient's life. After death the lungs are found highly congested and pervaded with miliary tubercle, soft in character, but devoid of caseation and containing abundant tubercle-bacilli; the bronchi are full of frothy mucus; and tubercle may be found in the pleura, peritoneum, or cerebral membranes, with effusion into the ventricles. This form is distinguished from capillary bronchitis by the presence of fever; from enteric fever by the different physical signs; from acute phthisis by the great dyspnoea and scanty expectoration; and by the head-symptoms (when present) from all the above.

Acute tuberculosis is the most fatal form of consumption, terminating in a few weeks or even days, and is characterised by gastric disturbance, by the presence of family predisposition (Pollock), and by the absence of hæmoptysis. It may be primary or secondary, but in each case is equally fatal.

2. Acute Phthisis.—The patient, generally young, who may have had a cough previously, is attacked with sharp pain in one side of the chest, quick pulse, high temperature, the skin being quite burning to the hand of the physician, alternating with night-chills and sweats. The general appearance betokens pneumonia, but the crepitation commences at the apices, extending to the whole lungs, and is not so fine and even as in pneumonia. The cough increases; the expectoration becomes opaque and purulent, containing quantities of lung-tissue and swarms of tubercle-bacilli; and the temperature assumes the intermittent type. The physical signs show at first gradual consolidation of both lungs, but later on indicate that excavation has taken place; and this continues, the patient rapidly wasting and dying in a few weeks. Sometimes the cavity opens into the pleura, which in these cases is rarely adherent, and death ensues by pneumothorax. This form is not quite so hopeless as acute

tuberculosis; and in some instances the disease may stop short of utter lung-destruction and become chronic, the patient remaining in a state of crippled respiration and of health for months and even years. Such cases may last for periods extending from three and a half to sixteen years. After death the lungs are found more or less consolidated, with adherent pleurae, the indurations consisting of red hepatisation and caseous infiltration, the latter largely predominating. Excavations abound in all directions, and but little or no miliary tubercle is present. The characteristics of this form are (1) the acuteness of the disorganising processes, excavation quickly succeeding consolidation; (2) the inflammatory nature of the lesions, and the rarity of miliary tubercle; (3) the occurrence of pneumothorax; and (4) the freedom of other organs from tuberculosis. An intermediate form is acute tuberculo-pneumonic phthisis, in which tuberculation predominates, but the tubercular masses soften rapidly, and tubercle forms at the same time in other organs such as the intestines.

3. Catarrhal Phthisis.—The patient has been subject for years, perhaps, to attacks of winter catarrh, which disappear in summer; and at last, owing to a severe season, or from his being in less favourable circumstances than usual, his cough does not cease, as formerly, but remains persistent, and is accompanied by some purulent expectoration, loss of flesh, and night-sweats. The bronchial *râles*, sonorous and liquid, as they disappear from certain parts of the lung, become more prominent and localised in others, especially under the clavicles, and above and between the scapulae. The *râles* become coarser, and the sonorous rhonchus assumes a croaking character. Signs of consolidation soon appear, but are never so prominent as in other forms, owing to the temporary emphysema accompanying bronchitis; the dullness appears in patches over the centres of increased rhonchus; the liquid *râles* diminish, owing to increasing obstruction, and give place to a tubular sound conveyed by the extending consolidation from the larger bronchi, and heard best in situations overlying them, as below the clavicle, and above and within the scapula, in the axillary and middle dorsal regions. The tubular sound has a sharp, whiffing character, and is often unaccompanied by bronchophony, from the consolidation being insufficient, and the bronchial tubes too choked to produce it. If the case goes on unfavourably, the expectoration becomes more abundant, and is found to contain both tubercle-bacilli and shreds of lung-tissue, and excavation is proved to have taken place, with the usual symptoms; the patient assumes all the appearances of advanced cavity-phthisis, and the case from this date can hardly be distinguished clinically from those of a strictly tubercular origin. After death the lungs are found to be more or less consolidated, the indurations taking the direction of certain lobules and generally not affecting entire lobes. The indurations are of a grey or yellowish tint, with numerous yellow masses of caseation intervening, which abound in tubercle-bacilli. Another form of catarrhal phthisis follows on attacks of unresolved pneumonia or of pulmonary affections tending to lung consolidation. Portions of the lung may be found in the first stage of catarrhal consolidation, so well described by Hamilton, with isolated lobules or groups of lobules of a leaden or purple colour, and the adjoining ones may be emphyse-

matous. Wedge-shaped patches of consolidation can be traced on the pleural surface, exuding on section yellow catarrhal fluid similar to that contained in the bronchi. Numerous excavations of irregular form are seen containing bacilli, but in most instances no trace of tubercle is to be found, though it is occasionally present. The bronchi are generally dilated, and full of purulent matter. This form is more common among the young than the old, and arises from whooping-cough, measles, and bronchitis, the pathology being extension of catarrh from the bronchi to the alveoli, implication of the interstitial tissue, large epithelial proliferation, causing pressure and emptying of capillaries, degeneration and caseation of the alveoli and their contents, and consequent excavation, with occasionally lymphatic infection.

4. Fibroid Phthisis.—This term, introduced by the late Andrew Clark, is applied to cases of which fibrosis is the principal feature. While this process accompanies most instances of chronic phthisis, it specially characterises those in which interstitial pneumonia is present, and entirely modifies their history and symptoms. It is generally secondary to attacks of pleurisy and pleuro-pneumonia, or to chronic pneumonia, resulting from long-continued irritation of the lungs, through the inhalation of dust or grit, as prevails among fork- and knife-grinders, colliers, and button-makers. See OCCUPATION-DISEASES.

A patient has an attack of pleurisy with effusion, from which he recovers with absorption of fluid; but percussion shows dulness over the whole side, and somewhat feeble respiration. The patient experiences dragging pains in the side; a dry, hacking cough, sometimes paroxysmal in character, with little expectoration, continues; and the breathing, always short, becomes still more so on exertion. These symptoms increase, and a few months later we find marked immobility of the affected side, dulness throughout, and now considerable shrinking, the circumference of this side measuring one or two inches less than the healthy side. On auscultation we notice the breathing to be very deficient in some parts, and in others bronchial, and sometimes cavernous in character; but generally there is everywhere absence of true vesicular breathing. Careful percussion of the opposite side of the chest shows the line of resonance to extend beyond the usual limit, passing to the edge of the sternum, and often an inch or two farther; demonstrating that the contraction of the affected lung has caused the healthy one to be drawn across. Other organs are likewise displaced. If the left lung be affected, the heart is tilted, not necessarily upwards, as when a cavity is contracting, but outwards. The stomach rises, its note being audible as high as the fourth rib. The heart is not only displaced, but is uncovered by the retreating lung; and the right auricle and ventricle are clearly distinguished by their pulsations. If the right lung is affected, the left may be drawn over, and the area of resonance may extend as far as the inner half of the right clavicle, and a line drawn thence sloping towards the middle of the sternum. The heart is transposed, and its impulse may be traced in the fourth interspace on the right side. The liver rises up to the fifth rib, and shrinking of the chest-walls takes place, as on the other side. The expectoration, if there be any, has rarely been found to contain

tubercle-bacilli. The pulse may be slow; the respiration often rapid, rising to 50 and 60 per minute. The temperature seldom rises above the normal and is sometimes subnormal. When the temperature rises over 100° F. it signifies that something beyond fibrosis is going on. The cough is troublesome and often induces vomiting; and the expectoration becomes more and more difficult, and in time, on account of retention, fetid. Meanwhile the dyspnoea increases, the other lung becoming involved; signs of obstructed circulation appear; dropsy of the extremities takes place, and rapidly increases; the urine becomes albuminous, and the patient dies, either of dyspnoea or of uræmic poisoning, his death contrasting strongly with the ordinary termination of consumptive disease. The patient may, however, die of apnoea, without albuminuria or dropsy. After death we find a lung contracted to the size of a man's fist, with enormously thickened and adherent pleura, and widely dilated bronchi, with interlobular septa much increased in size and encroaching on the lung-structure, which seems to be replaced by a hard fibrous tissue, in parts mottled with grey, deeply pigmented, and resembling cartilage in its resistance to the knife. Embedded in this structure are found caseous and cretaceous masses, or, again, excavations of various sizes; the walls of these and of the dilated bronchi being rigid and inelastic, from the presence of the fibroid material, and thus affording some explanation of the difficult expectoration and consequently troublesome cough. Careful examinations of microscopic sections of this fibroid tissue have, according to Andrew Clark, Watson Cheyne, and Percy Kidd, failed to detect tubercle-bacilli; but in the caseous masses embedded in it Watson Cheyne has found them. Besides these changes, we may find the other lung the seat of tuberculosis, though this is not constant; but commonly the bronchial glands are hardened and deeply pigmented. There is often amyloid disease of the liver, spleen, and kidneys.

5. Scrofulous Phthisis.—This is a variety where disease of the lung is preceded by, or accompanies, tubercular affections of various joints, caries of the sternum, ribs, and vertebrae, lumbar and psoas abscesses, otorrhœa, fistula in ano, or, as is most common, enlarged and caseating glands—cervical, bronchial, axillary, or mesenteric. Cases of secondary phthisis show an early infection of the lymphatic system, and a remarkable correlation appears to be established between the external gland or discharging surface and the condition of the lungs. If the glands are suppurating, or if the fistula is open, or if the carious bone freely discharges, the lung-disease will remain quiescent, and progress may be made towards arrest; but if, on the other hand, any of the above discharges, in the most of which tubercle-bacilli have been detected, should be checked, or cease *without the removal of the diseased tissue*, the lung-disease passes into fresh activity, making considerable advance and extension. This has been used as a strong argument against operating on fistula in ano if the lungs have been affected. The temperature-course in these cases, if active lung-changes are taking place, is remarkably fitful, showing evening exacerbations of 102° to 104° F. and morning depressions of 96° to 97° F.; and night-sweats are usually very profuse. Patients of this type lose and gain flesh

with great rapidity, owing probably to the pyrexia and fitfulness of the appetite.

6. Hæmorrhagic Phthisis.—This name is intended to designate, not phthisis arising from the results of hæmoptysis (*phthisis ab hæmoptoe*—Niemeyer), but a form recognised by C. J. B. Williams, Peacock, Hughes Bennett, and the writer, in which large and repeated hæmorrhage is the principal feature, associated with a small amount of detectable disease. It is more common among men than women, in the proportion of five to one; and the period of attack is later than in the ordinary forms, possibly owing to the element of heredity being generally absent. The patient may have had signs of failing health before the hæmoptysis, but often he is apparently in good health, when he is suddenly attacked with profuse hæmoptysis, the blood being florid, the hæmorrhage sometimes lasting many days, and always causing a reduction in flesh and strength. Cough and expectoration follow, yet examination of the chest only indicates slight signs, and sometimes none at all. When present they are to be found in the supra- or inter-scapular regions, or below the clavicle. The patient improves, and often entirely loses his cough before the recurrence of the hæmorrhage, which may not take place for days, weeks, months, or even years. If the attacks recur often, the cough becomes persistent; the expectoration, when not sanguinolent, is mucopurulent; wasting and night-sweats appear; and the physical signs now show unmistakable consolidation, which goes on to softening and excavation. In most cases the disease does not extend beyond consolidation, and large quantities of blood are expectorated without fatal results, the patients recovering in the intervals, and sometimes living to a considerable age. Peacock stated that in most instances some more or less exciting cause of a depressing character is to be detected, in the form of syphilis, cold, dysentery, bodily strain, exertion of voice; but the observer will often fail to find one. The exact pathology of this form of phthisis is uncertain, because few of the patients die in the early stage; but it is probable that the hæmorrhage is produced by the erosion of the pulmonary vessels by bacillary invasion, masses of tubercle-bacilli having been shown to be present in the walls of both arteries and veins; and in hæmorrhagic phthisis it is probable that the larger vessels are thus attacked.

DIAGNOSIS.—Phthisis is distinguished from other chest-affections by the presence of tubercle-bacilli in the sputum and by the evidence of physical signs. The evidences of consolidation separate it from bronchitis; while the tendency of the signs to become localised in the apices of the lungs, their special characters, and the combination of consumptive symptoms, distinguish it generally though not invariably from pneumonia due to other causes.

Of the various forms of phthisis, the most difficult to diagnose from other diseases is acute miliary tuberculosis, which at its onset is sometimes mistaken for acute bronchitis, from the fine *râles* and rhonchi accompanying the miliary formation. It has also been confounded with enteric fever, from the high pyrexia, the depression of the patient, and the occasional diarrhoea accompanying it; but in both cases the rapidly advancing symptoms, and the steadily progressing physical signs, such as increased and scattered crepitation, if frequent careful

examinations be made, ought to leave us in no doubt as to the nature of the case.

The diagnosis between acute phthisis and croupous pneumonia is not easy at the onset of these complaints, the physical signs not always sufficing for this purpose. In a short time, however, the detection of tubercle-bacilli, and later of lung-tissue in the sputum, and the rapid wasting, make matters quite certain.

The diagnosis of chronic tubercular phthisis from anæmia and chlorosis, sometimes confused with it on account of the amenorrhœa often common to both, is made by the physical signs; by the different kinds of pallor in the two diseases; and, lastly, in chlorosis, by the absence of wasting. The diagnosis of excavation in phthisis from bronchiectasis is by no means easy, as the position of the cavernous sounds is not always sufficient to determine the nature of the lesion. Dilated bronchi are found in the subclavicular and interscapular regions, and where ulceration is proceeding in bronchiectasis lung-tissue may be detected in the sputum; but the presence of tubercle-bacilli at once settles the question in lesions of phthisis, while the convulsive character of the cough, and the fetid expectoration, abundant, but mixed largely with air, generally enable us to decide in favour of dilated bronchi. The diagnosis from cancer, especially from sarcoma of the lung, depends partly on the symptoms, and partly on the physical signs which, in the case of sarcoma, present larger areas of dullness and generally of a more intense kind, and the remarkable shutting off of all breath- and voice-sound, which cases of lung-cancer present. See MEDIASTINUM, Diseases of.

DURATION AND PROGNOSIS.—Early detection of the disease, and improved treatment, have worked a great revolution in our ideas as to the *duration* of phthisis.

The statistics of C. J. B. Williams and the writer, founded on 1,000 cases among the upper classes, give an average duration in 198 deaths of 7 years 8·72 months; and in 802 living of 8 years 2 months. The fact of these patients having all been one year and upwards under observation necessarily excludes some of the acute cases; but with this limitation these figures, striking though they be, may be taken as a correct average for the duration of the disease among the upper classes under modern treatment, especially as 72 per cent. of the living had recovered sufficiently to pursue their usual avocations, and many among them had already lived upwards of twenty years since their first attack. The duration of the disease is found to be considerably influenced by age; for it is longer in proportion as the age of attack is later, this retarding influence being more conspicuous among males than females. Females are attacked earlier, and the disease in them runs a shorter course by nearly two years than among males.

Of the varieties of phthisis, acute tuberculosis is the most rapid in its course, generally terminating in a few weeks, or occasionally in a few days. Acute phthisis has hardly a less rapid course, though it may occasionally be retarded, the disease becoming chronic, and the patient surviving for many years. Catarrhal phthisis has an average duration somewhat below the average of eight years of ordinary phthisis. Fibroid phthisis, on the other hand, exceeds the ordinary duration by nearly two years. Hæmorrhagic and scrofulous phthisis are both of

long duration. These calculations are based on statistics of patients of the upper classes treated according to the best medical and hygienic treatment known; but if hospital cases are reckoned, the average duration of phthisis generally, and of its various forms, must be held to be much lower than the above estimate.

The prognosis in phthisis depends chiefly on the extent to which the system is infected, and especially whether or not other organs are the seats of tubercle. Cases of acute tuberculosis resemble closely those of pyæmia in their symptoms and fatal course, and only differ in the nature of the pathological products. Similar single-cavity cases, where the disease is strictly limited, bear a strong resemblance to chronic abscesses, which go on discharging for long periods, without materially curtailing the life of the patient. The future, therefore, of the patient depends to a great extent on whether the disease may be considered local or general, though of course we admit in both instances a constitutional predisposition, possibly of different degrees of intensity. Where the infection is rapid and complete, as in acute tuberculosis and most instances of scrofulous pneumonia, the prognosis is most unfavourable. Where, again, the disease is limited to one lung, and associated with similar processes in the joints, as in scrofulous phthisis, which act as diverticula to the central disease, the prognosis becomes far more hopeful, and the individual may last on for many years.

The prognosis in hæmorrhagic phthisis, where the pulmonary mischief is small and limited to the root of the lungs, is favourable, excepting of course the accident of death during an attack of hæmorrhage. The most favourable prognosis of phthisis must be retained for cases of inflammatory origin, for here the disease often remains limited for considerable periods of time, and the patient may live on, almost unconscious of it, to the natural term of life. If, however, the fibroid element be largely produced, a new danger arises from the obstruction to the circulation caused by the contraction of the lungs, which may be followed by dilatation of the heart, dropsy, and death.

The influence of *heredity* on prognosis lies in rendering the individual less resistant to the attack of the tubercle-bacillus; consequently he is attacked at an earlier age. Maternal inheritance is worse for the children of both sexes than paternal, for while the father transmits with the disease a certain degree of resisting power, the mother transmits with the disease the lack of resisting power which is the characteristic of her sex. The influence of *stage* must be duly taken into account, for statistics show a far more favourable prospect for mere consolidation than when a cavity is formed, and this is obvious from the increase of danger arising from two sources, namely, from purulent infection and pulmonary aneurysms. The use of mountain climates is believed to have largely improved the prognosis of tubercular consolidation, and to have increased the percentage of recoveries in this stage.

The grounds for an unfavourable prognosis are: (1) rapid extension of disease or of lung-excavation; (2) persistent afternoon pyrexia; (3) symptoms of great irritability of the gastro-intestinal tract, red tongue, diarrhoea, pain in the abdomen; (4) great wasting with, or without, pyrexia, combined with a good appetite; (5) strong hereditary predisposition; (6) the presence of albumen in the urine, with or

without some form of dropsy; (7) marked dyspnoea, especially if not warranted by the condition of the lungs; (8) the existence of considerable excavation in both lungs and the occurrence of pneumothorax.

TREATMENT.—The treatment of phthisis may be considered under four heads: (1) *treatment by inoculation and by anti-tubercular serum*; (2) *medicinal*; (3) *dietetic and hygienic*; and (4) *climatic*.

1. *Inoculation.*—In 1890 Koch introduced the treatment of phthisis by hypodermic injection of *tuberculin*, a glycerine-extract of a pure cultivation of tubercle-bacilli, in which the parasites had been killed; and maintained that early-stage cases could be cured after four to six weeks of this treatment. Subsequent experience from all parts of the world did not confirm this statement, but demonstrated that, while tuberculin had a strong affinity for tuberculous lesions in various organs of the body and gave rise to characteristic constitutional reactions, it caused breaking down of the tubercular masses, and of the lung-tissue in their immediate neighbourhood, fresh eruption of tubercle, and extension of old cavities, the sputum containing an increased number of tubercle-bacilli, and a considerable amount of lung-tissue. Virchow found in the necropsies of patients treated by this method various kinds of pneumonia, including what he termed 'injection catarrhal pneumonia,' and in one case tubercular meningitis, which he attributed to this treatment. By treating it with platinum chloride, Klebs extracted from tuberculin an albumose called tuberculocidin, along with certain alkaloids, and attributed to it the power of arresting tubercle; and these and other modifications of tuberculin have been tried in the treatment of phthisis, without any success. Koch introduced later on two new preparations, viz. Tuberculin O and Tuberculin T R, prepared by pounding in a mortar dried cultures of the tubercle-bacillus, adding distilled water, and then centrifugalising in a powerful machine. The clear fluid at the top is used for inoculation as O Tuberculin, and the residue again treated with water as T R Tuberculin. Both preparations are preserved by the addition of 20 per cent. of glycerine before injection. The experience of these preparations has not been altogether favourable. Maragliano, the writer, and others have treated tuberculous patients with anti-tubercular serum, produced by inoculating immune animals, such as horses, goats, and asses, with tuberculin and then withdrawing serum and injecting it into the patients, but the results have never shown any considerable amount of success.

2. *Medicine.*—The medicinal treatment must be directed to four objects: firstly, antiphthisical, to raise the standard of nutrition and to fortify the individual against the bacillary invasion; secondly, antiseptic, to promote the destruction and elimination of the Bacillus tuberculosis; thirdly, to reduce and allay the local inflammations and congestions which accompany and considerably complicate the tubercular changes; and, fourthly, to relieve the various urgent symptoms. The first object is carried out by tonics, such as iron, quinine, arsenic, the mineral acids, and, above all, cod-liver oil, which has been shown to be the most effective agent of all in improving nutrition and rendering the individual less liable to bacillary attack. Some precautions are, however, necessary to ensure its being tolerated for long periods. The pale oil should be preferred, and ordered in doses of from ʒj to ʒss shortly before or after meals. The best

vehicles for it are the vegetable bitters—such as gentian, calumba, quassia, nux vomica and strychnine, hop, camomile, and cascarrilla—combined with an acid or alkali, according to the state of the gastric mucous membrane, and rendered more palatable by the addition of tincture or infusion of orange-peel or syrup of ginger. Various other vehicles are used, such as milk, salt and water, lemon-juice, orange wine, and sherry; while many patients, especially children, take it best in an emulsion, composed of cod-liver oil, a few drops of liquor potassæ or liquor ammoniæ, with an essential oil, like that of cloves or cinnamon, to cover the taste. In the great majority of cases cod-liver oil is well borne, if exhibited with discretion. Other oils are of use, but few equal the cod-liver oil in efficacy, on account of its great penetrative power, and of its forming with the biliary and pancreatic juices a compound easily absorbed by the lacteals. Malt Extract and similar preparations, though of greatly inferior nutritive power to cod-liver oil, often cause increase of weight, chiefly by assisting the patient to digest more starch, and are often with advantage combined with cod-liver oil, forming a palatable compound; but the stimulating quality of the malt sometimes causes increase of the patient's cough, and does not augment appetite. Of greatly inferior utility to the oil are the preparations of phosphorus and sulphur.

In France the sulphur-springs of Eaux-Bonnes, Cauterets, Bagnères-de-Luchon, and Bagnères-de-Bigorre are largely frequented by consumptives, the ground of this treatment being that the results of Claude Bernard's experiments show that sulphur, when absorbed, is excreted through the respiratory mucous membrane. Peter considers that any benefit that may accrue is owing to the influence of sulphuric acid on the catarrhal conditions. Arsenic appears to exercise a most beneficial effect in those consumptives who can digest it, and often under its influence fever and night-sweats disappear, and weight is gained; and the arsenical waters of Mont Dore, La Bourboule, and Royat are much frequented by consumptives.

The second object of treatment is antiseptic. The admixture of antiseptics with tuberculous sputum and other tuberculous material has rendered the inoculation of guinea-pigs and rabbits with them harmless; such are sulphuretted hydrogen, iodide of mercury, corrosive sublimate, iodine, carbolic (3 per cent.) and boric acid, helenin, creosote, phenyl-acetic and phenyl-propionic acids, and sulpho-carbolate of sodium. Some were actually mixed with tuberculous material, and then injected; others were injected afterwards, separately from the virus. All, when used in sufficient strength, were successful in checking the evolution of the disease in animals, and have been used in consequence in phthisis; but only with very moderate success. Moist heat is, however, the most powerful bactericide; tuberculous sputum can be rendered innocuous by exposure to a boiling temperature. The application of antiseptics has been made—(1) through the air-passages by sprays, inhalations, and 'antiseptic respirators'; (2) by hypodermic injection; (3) by injection *per rectum* of sulphuretted hydrogen and carbonic acid (Bergeon); (4) through the stomach as medicines; and (5) by intra-pulmonary injections through the wall of the thorax into tubercular cavities. It cannot be affirmed that any of these forms of anti-

septic treatment have succeeded in destroying the bacillus or in counteracting the effect of the ptomaines which it is supposed to propagate; and far better results have been obtained by constitutional measures which render the individual less vulnerable to bacillary attack.

The third object of treatment, the reduction of local inflammation, is best accomplished by mild antiphlogistic means, such as salines, with or without antimony; and counter-irritation to the chest-wall by blisters, iodine, or vesicating liniments, mustard, or the milder but still effectual application of linseed-meal poultices. Steady continuance with these will often render sedatives for the cough unnecessary. The *pyrexia* in many cases does not require special treatment, but will subside under the general measures directed towards the reduction of local inflammation. Where this is not the case, and the excessive temperature, rising to 103° to 105° F., torments and wastes the patient, the best method of reducing it is by the open-air treatment to be mentioned presently.

The fourth object, namely, the palliative treatment, includes that of the various urgent symptoms.

The *cough*, when not reduced by the counter-irritation, may be to a certain extent allayed by a combination of sedatives, such as opium and its alkaloids, conium, henbane, diluted hydrocyanic acid, American cherry, with mild expectorants, of which spirits of chloroform, lemon-juice, and squill are examples. Where the cough is frequent and the expectoration difficult, and there is proof of active disease, tubercular or pneumonic, proceeding in the lungs, an effervescing saline, containing carbonate of ammonium, with small doses of opium and antimonial wine, taken two or three times at night, will greatly relieve the symptoms, the rule in the treatment of consumption being to restrict the sedatives, as far as possible, to the night, so as not to interfere with the appetite and digestion. The preparations of tar, in the form of capsule, pill, or solution, are useful in reducing profuse expectoration. The inhalations of iodine, compound tincture of benzoin, carbolic acid, creosote, larch, and turpentine are useful if expectoration is offensive or requires stimulating; or, again, those of chloroform, conium and hop, when the cough is convulsive and dry.

The *pains* in the chest may be alleviated by blistering, painting with tincture of iodine, or stimulating liniments, such as turpentine and ammonia; or else on Frederick Roberts's plan, by securing the immobility of the side by strapping.

Night-sweats, when profuse, may be reduced by oxide of zinc (gr. ij to iv), by gallic or sulphuric acids, by sulphate of iron, by arseniate of iron (gr. $\frac{1}{6}$ to $\frac{1}{4}$), or most effectually of all by the preparations of belladonna, in the form of the extract (gr. $\frac{1}{4}$ to gr. i), or as the solution of sulphate of atropine (m j to ij), or used hypodermically; but these often cause dryness of the mouth and fauces. Dover's powder in 10 gr. doses is useful, but nitrate of pilocarpine (gr. $\frac{1}{30}$), and picrotoxin (gr. $\frac{1}{60}$) in form of a pill, are more effectual.

Diarrhœa, where due to bilious derangement and an acid state of the *primæ viæ*, is best treated by mercurial aperients, combined with carbonate of sodium or lime-water. Where it partakes of the nature of a flux, accompanied by a pale tongue and great debility, it may be checked by astringents, such as hæmatoxylin, catechu, krameria, baël, and

carbonate or subnitrate of bismuth. When ulceration of the intestine is present, it is generally but not always characterised by a red, irritable tongue, pain and tenderness of the abdomen, and persistency of the diarrhoea. Here, as in other forms of ulceration, opium and its alkaloids answer best, and may be given internally with sulphate of copper (gr. $\frac{1}{4}$ to $\frac{1}{2}$) every three or four hours. When the stomach is too irritable to tolerate medicine by the mouth, opium or morphine suppositories are useful, but still better are opiate enemata, which, acting more directly on the ulcers, check the pain and diarrhoea, and often afford considerable relief. The amount of injection to be used at a time must be regulated by the probable extent of ulceration; and as a vehicle, in cases of irritability, linseed tea will be found most serviceable. In very obstinate cases tannic acid (four to five grains) and acetate of lead (three to four grains) may be added to the injection. The opposite state of bowels, namely, constipation, is very common in the early stages of phthisis, and is best corrected by changes in diet, such as the use of brown bread and oatmeal, cooked and fresh fruit, regular exercise, and, if these prove insufficient, a mild aloetic or rhubarb pill, or the use of some mineral water, as Friedrichshall, Pullna, Carlsbad, Æsculap, Rubinat, Hunyadi János, and others.

The *dyspnoea* of advanced cases generally arises from difficulty of expectoration and the greatly curtailed respiratory power, and may be relieved by spirit of ether, carbonate of ammonium, and other diffusible stimulants, or by the inhalation of oxygen or of iodide of ethyl (capsules *m iij* to *v* for inhaling). The pain arising from perforation in pneumothorax is best treated by diffusible stimulants, and strapping the side to limit the movements of respiration; and if much liquid effusion or accumulation of air takes place, it is sometimes advisable to tap the chest; but, as a rule, the state of the patient does not allow of very active measures.

Bed-sores should be prevented by the use of a spring- or water-bed, and the skin of the dependent parts can be fortified by a lotion of spirit and water (1 part in 4). If a bed-sore has formed, it is best to protect it from friction by the use of circular air- or down-cushions, or thick felt-plaster, and the raw surface can be painted with collodion, or be regularly dressed.

3. *Diet*.—The great object being to introduce as large a quantity of nutritious food as can be digested, abundance of meat, plainly cooked, with fresh vegetables, and a fair amount of bread and starchy food, should be given. Fatty material, if it can be digested, should be largely represented in the dietary, and many physicians advise large quantities of cream, butter, and suet. It is found that under the open-air treatment very large quantities of all kinds of food can not only be taken but also assimilated by patients who are credited with weak digestions, and immense gain of weight amounting to 2 st. and 4 st. follows. Milk is the principal item, from 3 to 5 pints a day, with three large meat-meals, with abundant vegetables and bread-stuffs. When cow's milk disagrees, ass's or goat's—the unpleasant flavour of the latter disguised by orange-flower water—may be substituted with advantage. Koumiss and Kéfir, prepared from fermented mare's or cow's milk, are frequently used in Germany and Russia, but

they have not become popular in this country. The digestive powers being, as a rule, weakened, much good may be done by the addition of animal ferments, such as liquor pepticus and liquor pancreatis, to the food, which, becoming peptonised, is much more easily assimilated (*see* PEPTONISED FOOD). In the early stages stimulants are not largely required, as they increase the cough and pulmonary irritation; but when the strength fails, and the powers of digestion are weak, they may be given frequently in the form of brandy or whisky, and advantageously combined with liquid nourishment, such as eggs, soups, various meat-essences and panadas, arrowroot, and jelly. When wine is required, in chronic cases, it will be found that claret, hock, sauterne, and chablis tend to irritate the cough less than the stronger wines. Champagne should be given where the prostration is great, and it often is useful in aiding expectoration. In cases of laryngeal phthisis where the dysphagia is urgent, it is often advisable to feed the patient by nutritive enemata or suppositories.

Hygiene.—The consumptive patient should inhabit a well-ventilated, well-drained house, built on a dry soil, sand or gravel, sheltered from cold winds and well exposed to the south, not hemmed in by trees, the most suitable for the neighbourhood of the house being of the *Conifereæ* order. The bedroom should be lofty, provided with a fire-place for warmth and outlet ventilation; and the cubic space should be 1,500 to 2,000 cubic feet per head. The window should always be open night and day. Chowne's or Tobin's tubes must be employed to supply fresh air, even in stormy weather. Both bedroom and sitting-room should be exposed to the sun's rays, for the vivifying influence of which there is no substitute; and it is well to secure for the patient himself their benefit as long and as often as possible. All consumptives should be placed on the open-air system as early in the disease as possible, and the greater part of the day should be passed, not in the sitting-room, but reclining on a sofa or couch in a balcony, shelter, or 'Liegehalle,' under the full influence of the air, though protected from sun and weather. Patients in the prone position well covered with wraps endure with impunity the most severe cold and benefit greatly by this method of treatment. Pyrexia, often of long continuance, subsides in two to three weeks under this treatment when combined with large feeding. The sputum should be received into a vessel containing a disinfectant, to be frequently emptied, or it may be burnt, as is done at the Hospital for Consumption and Diseases of the Chest, Brompton.

Clothing and Exercise.—The underclothing should be woollen, either flannel or lambswool, or perhaps in summer merino may be allowed, the object being to secure a good non-conductor of changes of the temperature, which will at the same time absorb cutaneous moisture. The rest of the clothes must be adapted to the season, the invalids, male or female, always bearing in mind their greater liability to catarrh than ordinary persons, and using wraps freely, more especially when driving. The wearing of respirators, though undoubtedly a protection against cold, is not always desirable, as, unless the wire meshes are widely separated, they considerably impede free respiration, and form a kind of muzzle. A woollen scarf passed over the mouth and nose, in the fashion of

omnibus-drivers, or for ladies a good Shetland veil or 'fleecy cloud,' answers the same purpose without obstructing respiration.

Exercise must depend on the stage of the disease and the strength of the patient. In the first stage, especially when the disease is limited to one lung, and no fever or hæmorrhage is present, active exercise in the form of walking is advisable. Graduated ascents, as are used at Davos and Nordrach, are excellent when regulated by the medical attendant. Under careful superintendence, certain gymnastic exercises may be of benefit, which, by raising the arms, lift the upper ribs and increase the size of the thoracic cavity, especially in the upper regions, and thus necessitate a larger inspiration of air; and in time this leads to further development, and even to hypertrophy of the healthy lung. Emphysema may be produced in the diseased lung by this means, which is useful in limiting any further advance of infective tubercular disease.

Riding is excellent for a large number of patients, being intermediate between the active and passive varieties of exercise. Where the disease is more extensive and advanced only the passive forms of driving and sailing are possible.

4. *Climate*.—The main point to be held in view is to give the consumptive a climate in which he can live an open-air life and take abundant outdoor exercise, and experience that amount of stimulating influence which, while it improves his appetite and powers of digestion, does not irritate the mucous membrane of the lungs or increase the cough. The selection is generally difficult, and not only depends on the class of cases, but must be sometimes modified by individual peculiarities. *See CLIMATE, Treatment of Disease by.*

The writer's statistics, founded on 251 consumptives, who passed one or more winters in warm climates out of England, assign the most favourable results to sea-voyages, and next to Egypt and other dry climates. The Mediterranean basin, including Riviera, Malaga, Algiers, and the islands of this sea, follows next in point of success; while the moist temperate climates of Pau and Rome give far less good results, and Madeira only slightly surpasses these. The same statistics show the foreign health-stations to be on the whole more successful in prolonging life than the English ones; but we must not forget that the most advanced cases fall to the lot of the latter on account of the difficulty of travelling; and, on the other hand, a great advantage enjoyed by the home stations is the superiority of the food, which may in some degree compensate for the smaller number of days in which exercise can be taken, and the greater vicissitudes of weather. Of the British Channel health-resorts the more easterly, such as Hastings, Ventnor, and Bournemouth, have afforded more favourable results than Torquay and Penzance. It is impossible in a few sentences to lay down rules for climate selection, but a few general outlines may be given of the suitability of different groups of agencies.

The British south-coast stations are beneficial in scrofulous phthisis, and in many cases where the appetite is poor, and tendency to catarrh not the prevailing feature. They are beneficial too in cases of chronic limited cavity. In the catarrhal form of phthisis the Canary Islands, Madeira, and the West India Islands, especially the Blue Hills of Jamaica, are advantageous; the combination of

warmth with saline influence, and the absence of stimulating qualities, seeming to answer best.

Dry stimulating marine climates, such as the Riviera and Malaga, are recommended in phthisis supervening on inflammatory attacks, and in all cases where it is desirable to combine stimulating influence with a moderate degree of warmth, and decided dryness of atmosphere. Where greater warmth with a little more moisture is required, Algiers, and the islands of Corsica, Sicily, and Corfu will suit better. As better examples of warm dry climates may be instanced those of the Pacific—of Sierra Madre, Coronado Beach, Santa Monica, and Los Angeles.

Where the stimulating influence is undesirable, as in patients of excitable temperament, or irritable gastric mucous membrane, the *very dry inland climates*, like those of Egypt or South Africa, are preferred.

Sea-voyages to South America, Australia, and New Zealand, round the Cape, or the shorter one to the Cape itself, are indicated in cases of hæmorrhagic phthisis, of scrofulous phthisis especially with fistula in ano, of phthisis with emphysema, in cases of limited first or third stage, where the strength is unequal to much exercise, and where the patients have suffered from over-work or close confinement in crowded cities. *See SEA-VOYAGES.*

High altitudes.—The considerable mass of testimony in favour of this form of climatic treatment for consumption, in Europe, Africa, and North and South America, has rendered it the most popular climatic treatment of the day. The writer's statistics of 247 consumptives treated in Davos, St. Moritz, Colorado, and the South African highlands show that in unilateral tubercular consolidation more or less extensive improvement occurred in 97½ per cent., and complete arrest of the disease in 66¾ per cent., and that even in bilateral cases the percentage of arrest was 40. The results in cases of excavation were not so favourable, about 54 per cent. improving and 35 per cent. becoming worse. These results are the most favourable, but it must be remembered that the greater part were achieved in incipient and limited cases after residences varying from months to years. These patients are, however, liable to relapse, as occurred in a certain number of these cases.

At present the Andes, the Rocky Mountains, and the Alps, and even the South African highlands, are frequented by consumptives; but the conditions of temperature and altitude manifestly vary greatly, and while the climates of Quito and Santa Fé di Bogota resemble in temperature that of Malaga, the winter extremes of Davos and St. Moritz in the Alps are more nearly akin to those of Canada. The Colorado climate is a very sunny mountain climate, with considerable extremes, but drier than the Swiss. In all these places, however, there exists a distinctly specific influence apart from that of heat and moisture, in the form of diminished barometric pressure, producing rarefaction and diathermancy of the atmosphere, which is shown in the patients residing at high altitudes. The chest becomes expanded, and hypertrophy of the healthy lung-tissue takes place, accompanied by vesicular emphysema around the lesions. Patients with tubercular consolidation of one or both lungs, provided the lesions admit of sufficient lung-surface for proper aëration, the powers of the circulation be sufficiently good to allow of exercise, and there

be no pyrexia, are the proper cases for this form of climate, and in many of such complete arrest of the disease may perhaps be predicted. These high altitudes are also suited for hæmorrhagic phthisis or phthisis of distinctly hereditary origin, provided it be not too advanced; and they are contra-indicated in (1) patients of advanced years, (2) catarrhal and laryngeal phthisis, (3) phthisis with albuminuria, (4) phthisis with double cavities, and wherever the extent of the disease or the condition of the lung places the patient in the category of 'advanced cases.'

C. THEODORE WILLIAMS.

PHYSICAL EDUCATION. — **INTRODUCTION.**—*Physical education* concerns itself with the fullest development of the body, just as education, in the general sense of the term, has for its object the fullest development of the manifold qualities of the mind. A child of normal faculties brought up in the midst of a civilised people, and deprived of systematic teaching of any kind, would, when manhood was reached, exhibit a degree of intellectual development which might surprise those who can conceive no mental worth unless it be the product of the pedagogue. An individual thus left to himself would learn much from observation, experience, and example, but the methods of his mind would be clumsy and imperfect, and he would lack those arts whereby knowledge can be economically and systematically acquired and conveniently employed. He would, in fact, remain imperfectly developed, and would have missed the opportunity of making the best of his faculties.

It is precisely the same with the physical development of the body, if it still be assumed that the individual is born among a civilised people. To simply leave a child to his own devices when he is not engaged in school work, is not to provide him with a sound or even an efficient education of the body. It must be borne in mind that the modern child has departed very far from the primitive savage, and that his environment, the claims upon his energies and the trammels of civilisation, no longer render it possible to leave the perfecting of his body solely to 'nature.' It cannot even be said that the physical development of the higher races of savages, when mythological matter is excepted, leaves nothing to be desired.

Physical education, therefore, to be of the highest service, must be precise and systematic, must be graduated and progressive, and must be adapted to the personality of the individual. It must be conducted, indeed, upon precisely the same lines as is the better formulated education of the mind.

Physical education involves exercise and movement. Save by exercise, there is no means of developing any portion of the organism, even provided that the supply of food and of air be sufficient. Exercise means growth, functional vigour, and the maintenance of a high standard of organic life. Undue rest is followed by feebleness and decay. Absolute rest is found only in death.

It is assumed in the present article that exercise is confined within proper limits. The subject of the abuse of physical exercise is dealt with in another article. See EXERCISE.

1. The effect of Exercise upon the Body.—Exercise increases the size of a muscle, the stoutness of its tendon, and the power it can command. The stronger the muscles, the finer and denser are the aponeuroses with which they

are connected, and the firmer are the fasciæ which hold them in position. Muscles act upon articulations. The duly exercised joint has a good covering of cartilage, powerful ligaments, and well-developed bony parts. Exercise, moreover, influences the size of the bones upon which the muscles act, renders them stronger and denser, and emphasises their anatomical details.

Exercise induces a more vigorous respiration, and under increased breathing-efforts the lung-capacity and the size of the thorax are augmented. It accelerates also the blood-circulation, and the effect of an increased blood-supply upon the size and condition of the tissues concerned is well known.

The secret of the size and proportions of the future man lies buried in the ovum from which the individual is developed. The child of short and stunted parents will probably also be short and stunted, and remain so in spite of an elaborate physical training.

The effects of systematised exercise upon the growth and development of the body have been demonstrated by many observers, and have been expressed in the form of actual measurements by Maclaren and others. In the *Report* of the Anthropometric Committee, the measurements of eighty-nine professional and amateur athletes are given, with the following results: 'Their average stature exceeds that of the general population from which they are drawn by 0·68 inch, while their average weight falls short of that standard by 14·5 lb. The ratio of weight to stature is 2·100 lb. in the athlete, 2·323 lb. in the general population, for each inch of stature.' See also Cecil Hawkins's monograph on the Physical Examination and development of public-school boys.

In noting the effects of physical exercises by means of measurement, the most conspicuous attention is drawn to the increase in height and in the circumference of the chest. In young subjects there is strong evidence in support of the belief that systematised exercise may actually increase height. In cases in which the training has been commenced after the growth of the body has ceased, any increase in stature is to be ascribed to a straightening of the spine and an improved carriage.

In considering the general question of increase in chest-girth, care must be taken not to ascribe this improvement—as some are apt to do—entirely to an increase in the capacity of the thoracic cavity. This is probably in all cases of much less effect than muscular development. In measuring the chest, the tape passes over those very muscles which are prone to the most conspicuous development in those who practise gymnastic exercises, for example, the pectorals and the great muscles passing from the trunk to the upper limb. The effect of proper exercise in augmenting the respiratory capacity to a certain degree is, however, undoubted.

A physical training does something more than merely increase the size of the limbs, and add to the stature. It tends to render all parts of the body symmetrical, and more perfectly proportioned. Of all animals, man is the most subject to variations in proportion and symmetry. Not only do children often grow in a fitful and irregular manner, but they may exhibit unequal developments, one side appearing to be larger than the other. Such deviations, which are distinct from actual deformities, a well-directed system of training will usually correct.

There must needs be a limit to the growth of muscles, and those exercised to too great a degree will, after attaining a certain size, commence to waste.

Moreover, from exercise there result an increase in the contractile force of the muscles, and an improvement in the speedy and complete contraction of their fibres. The muscles of an athlete when in training contract with extraordinary force under the electric current; the muscular sense is developed to its utmost; the perfection of the reflex act is attained; the power of co-ordination possessed by the individual is augmented; and movements at one time complex and difficult are carried out with ease. In this way the nervous system is saved a great expenditure of force.

One conspicuous feature in muscular training is the increase in the possibilities of automatism, and another remarkable element is the economy of force which results from muscular education. He who has been well trained physically, possesses not only a complete, but an intelligent, use of his muscles. His movements are powerful, are under absolute control, are precise, and capable of the finest and most elaborate adjustment. The art of the athlete consists not in employing the greatest amount of power in effecting a movement, but in carrying out that movement with the least possible expenditure of force.

Not only does a systematic training promote the fullest growth of the body, and help the individual to attain to something approaching a perfect symmetry, but it gives to him an easy and graceful carriage, and a bearing which has about it the mark of vigour and completeness. With suitable exercises, the shuffling and shambling gait disappears, the loutish boy ceases to look loutish, and the gawky girl no longer excites comment, rounded shoulders become square, and bending backs are made straight. The athlete, so far as his body and his personal equation are concerned, has reached the full and perfect stature of a man; and the girl whose physical education has been complete, reaches her point of physical perfection as a woman. It must not be forgotten that the beauty of the body depends upon a fully formed skeleton and perfectly developed muscles, and not upon deposits of fat.

The tissues of the ill-developed are flabby and lacking in elasticity and consistence; those of the well-developed are, on the other hand, firm, resisting, and full of evidence of living. The delicate and sensitive complexion of a young woman whose physical training has been efficient is in conspicuous contrast with the dull lustreless integument of the individual who 'never stirs out of the house.' The skin of the recluse is grey, greasy, and unpleasant-looking. Exercise involves more living in the open air, a freer and deeper respiration, and the coursing of a more vigorous flow of blood through the integuments. In the matter of personal comfort, no greater sense of pure pleasure can illumine the human mind than that which results from perfect health; and such health cannot be attained without a full exercise of the manifold energies of the body. He who takes no exercise remains an imperfect creature—he misses at least one-half of the delights which are available to man during a comparatively short existence, and it is not to him that 'joy cometh in the morning.'

2. The effect of Exercise upon the Mind. Moderate, regular, and systematic exercise, by

stimulating the circulation of the body, improves also the circulation of the brain, and is therefore an aid to cerebral movements. By improving the health and physical strength it increases the capability of the individual for mental work, and for the physical strain consequent upon mental concentration. It offers, too, an admirable change of employment, and in this way becomes a valuable means of rest. 'Prescribe fencing, gymnastics with apparatus, and lessons in a riding school,' writes Dr. Lagrange, 'to all those idle persons whose brain languishes for want of work. The effort of will and the work of co-ordination which these exercises demand will give a salutary stimulus to the torpid cerebral cells. But for a child overworked at school, for a person whose nerve-centres are congested owing to persistent mental effort in preparing for an examination, we must prescribe walks or rides, the easily learnt exercise of rowing, and, failing better, the old game of leap-frog and prisoner's base, running games—anything, in fact, rather than difficult exercises and acrobatic gymnastics.'

An excessive and absorbing indulgence in physical exercises is undoubtedly bad, and it may be that in some public schools too great significance is attached to mere athleticism. The all-engrossing pursuit of athletics tends to make the individual too much of an animal, and to afford neither time, opportunity, nor suitable conditions for the development of his brain. Still, on the other hand, in these days of cramming and intense competition, many a man can base his success in life upon physical health before all things; and there are not a few who have attained to eminence among their fellows who have to thank Providence for the tardily recognised blessings of an idle youth.

The systematic and properly arranged pursuit of physical exercise tends to develop certain admirable qualities, and notably those which are so much prized among Englishmen, and which are well designated as 'manly.' These qualities are brought out in those who are enthusiasts in outdoor sports and games. The football-player has done more than merely develop his muscles; and the man who has rowed in his college eight has learnt something beyond the mysteries of the sliding-seat. Such lads and men have learnt in a school where the principles of pluck, courage, endurance, and self-reliance are acquired. They will have learnt to be ready, to be quick of eye and hand, and prompt in judgment. They will have appreciated the value of discipline and of self-control. They will have felt the inspiration of the chivalry of days gone by, and have experienced the influences of good fellowship and loyal comradeship. They will probably have learnt what it is to be patient, to be fair, to be unselfish, and to be true. The following utterances by the head-master of a large public school in England are worthy of note: 'The worst boys intellectually, physically, and morally are the loafers.' 'The boys who work hard and play hard do not ape the vices of men, and are free from the insidious evils that often fasten on unoccupied boyhood.'

3. The Elements of Physical Education.

(a) *The exercises should be adapted to meet the needs of each individual case.*—The object of a proper physical education is to develop health and not mere strength, to bring the body to its highest degree of perfection, and not to convert children and youths into gymnasts and acrobats. Its prin-

principal purpose is to best fit the individual for the duties and work of life, and not to elicit proficiency in mere feats of skill and adroitness.

It must not be forgotten, moreover, that individuals vary greatly in the quality of their physical powers, and in their capacity for muscular exercise. It is just as impossible to form a great mass of children into one gymnastic class as it is to place those children in one school standard under one teacher. Neither age, height, size, nor sex affords sure means of classifying children, so far as the needs of a proper physical education are concerned. Each individual must be considered upon his or her own especial merits, and there is no method of physical training which is universal or all-sufficing, and adapted for all sorts and conditions of human beings. The sending of a child to a gymnasium, or the placing of it under the care of a drill-sergeant, is as crude a procedure as the conducting of a child within the walls of the first school met with, and leaving it there with the impression that it will somehow be educated. Physical education requires as much care as does mental education, and calls for as much subdivision both in the teaching and in the taught. Before planning out a course of instruction, a child's physical condition should be inquired into with as much care as is exercised in examining an adult for life-insurance.

(b) *The exercises should be carefully devised, systematically arranged, and suitably graduated.*—The exercises should be planned upon a definite system, should be suited for the individual, and should aim at the equal employment of all the muscles, and not at the development of a few. The work in an ordinary gymnasium tends to throw strain mainly upon the upper extremities, while most of the outdoor games tend to develop the lower limbs. No great good can be obtained from tedious drilling and purposeless marching, and the time devoted to physical training should never be so absorbing as to allow no leisure for games and other pleasant forms of recreation. It is desirable that the lessons should be as varied and as interesting as possible, and that reasonable opportunity be given for competition, and the encouragement of those who are specially fitted to excel. In every instance violent intermittent exercises should be forbidden, and the performance of feats of strength should never come within the scope of the education scheme.

(c) *The exercises should be carried out under proper guidance, and with suitable and efficient apparatus.*

(d) *The time for the exercises should be carefully selected.*—Violent exercise after a full meal is obviously bad, and a course of physical instruction should not be carried out in the case of children who are tired from a long day's attendance in school, or who are feeble from want of food.

In the matter of schools, it is well that the period for physical training should be interpolated among the hours devoted to ordinary school work. The Rev. Dr. Warre, of Eton, advises that a schoolboy's day should be disposed of as follows: Rest, ten hours; work, seven hours; meals and play, seven hours.

So far as adults are concerned, the taking of violent exercise in the evening, after a long and arduous day's work, is often injurious in its result. There is no better time for such individuals than the early morning.

(e) *Exercises, so far as is possible, should be taken in the open air, or in a large and well-ventilated room, and the subjects of the instruction should be properly clad.*—The atmosphere of many gymnasia and fencing saloons is, especially in the winter-time, close and unwholesome. The garments worn should be light, loose, and always made of wool.

4. The Selection of Exercises according to Individual Needs.

Children.—The physical training of the child should be commenced early, should be made as interesting as possible, and be represented in the main by what may be termed scientific romping.

The exercises should be given, whenever possible, in classes.

The set exercises should not be too formal, and never be too long; and in no instance should they be allowed to take the place of the ordinary outdoor games of children.

Games which involve shouting should be encouraged, and a very prominent position given to running, skipping, games with balls, and jumping.

The most rudimentary of all games, 'touch,' is one of the most excellent. The upper limbs may be encouraged by such amusements as battledore-and-shuttlecock, and the lower by such a game as hop-scotch.

The set exercises should take the form of what are known as Swedish gymnastics, the vocal march, musical drill, and the class exercises with dumb-bell and bar-bell.

Children should avoid exercises of strength; and, in the main, exercises of speed. There is little need for especial gymnastic apparatus. Those best suited for children are the climbing-rope, the inclined ladder, the vaulting-horse, and the parallel bars.

Girls and Women.—The physical condition of a large proportion of the girls and women in this country is quite deplorable, especially among the middle and upper classes. It is apt to be ascribed not to a totally neglected education, but to the belief that growing girls are always awkward, uncouth, and weedy. This belief is not well founded.

The girl is too often encouraged to be dull, to be prim, to be subdued, to suppress the outbursts of pure animal spirits. She is more or less under the curse of that detestable adjective, 'lady-like.' She spends hours in an ill-ventilated schoolroom and upon a piano-stool, and the rest of her time is occupied in eating and sleeping, in preparing lessons, in stooping over needlework, and in taking formal walks with the governess.

A good digestion and vigorous lungs are more useful to a woman in the battle of life than a knowledge of advanced mathematics; and sturdy limbs and strong hands are of more value to the mother of children than even decimal fractions and a familiarity with irregular verbs.

Younger girls may pursue the exercises named in dealing with the education of children. Those who are a little older have an infinite variety of healthy pursuits at their service—running, skipping, outdoor games, riding, skating, swimming, cricket, games with balls, archery, tennis, and certain exercises in the gymnasium. They should practise also such movements as develop the abdominal muscles, and should never neglect rowing.

Fencing is good; a tendency to flat feet and weak ankles may be met by such games as hop-scotch, by step-dancing, and the hornpipe.

Cycling may be practised in moderation. Jumping is probably not advisable for girls who have passed the period of puberty.

For women, such exercises as have just been detailed are open, with the obvious modifications which their age and dispositions suggest.

Lads.—Lads between fourteen and eighteen have almost every form of exercise and physical recreation open to them. They should avoid feats of strength, paper-chases, and exercises of extreme speed, such as sprint-running, which are apt to cause strain of the heart as well as other kinds of injury.

Adults.—Adults between eighteen and twenty-five have the whole of the joys of the athletic world open to them, and if a man keep in training and in practice his period of athletic life may be extended to thirty. The middle-aged and elderly must anticipate a progressive curtailment of their more active pursuits. There remain, however, walking, and all the milder forms of outdoor exercise—riding, rowing, skating, cycling, golfing, and the use of the simpler gymnastic apparatus. After thirty, few men are capable of undertaking exercises of speed without actual risk.

FREDERICK TREVES.

PHYSICAL EXAMINATION.—The object of a physical examination is to ascertain the precise seat, limits, and characters of those evidences of disease which are recognisable by our senses, and which are called physical signs. In the present article a description will be given of the physical examination of—(1) the Patient Generally; (2) the Respiratory System; (3) the Organs of Circulation; (4) the Mediastinum; and (5) the Abdomen. *See also* NERVOUS SYSTEM, Clinical Examination of.

I. General Survey.—Our attention will first of all be naturally attracted to the *physiognomy* of the patient, that is, to his general appearance and build. We note his apparent *weight* and *height*, and, if possible, correct our observation by scale and measure. We observe the *state of nutrition*, firmness or laxness of muscle, corpulence, thinness, emaciation—atrophy of any particular muscle or group of muscles. The *complexion* of the patient is to be remarked, whether clear, sallow, dark, fair, jaundiced, or pigmented: also lividity or pallor of surface and mucous membranes. The *apparent age* as contrasted with actual years of the patient; elasticity of features, condition of hair, presence of arcus senilis. The *symmetry* and *play of features*, the expression whether of vivacity, despondency, suffering, anxiety, paralysis, or hysteria. *See* PHYSIOGNOMY.

While making these preliminary observations, a general outline of the history of the patient and of his present illness will have been elicited.

The *pulse* should next be noted (*see* PULSE). We may, in important cases, extend our inquiries or record our observations by means of the sphygmograph. *See* SPHYGMOGRAPH.

The *respiration* of the patient requires attention as regards rapidity; mechanism, that is, whether abdominal or thoracic in normal proportion; rhythm, regular or irregular, easy or laboured; and freedom or otherwise from pain. The action of the nares, and any recession or otherwise of soft parts during respiration, should be especially observed.

In health and under physiological conditions of age, exercise, emotion, &c., there is a tolerably constant ratio between the respiration and pulse-rate, namely, one respiration to from three to four pulse-beats. In disease this ratio is often much altered. The average respiration-rate in a healthy adult is from 17 to 20 per minute, in the infant about 40 per minute, between one and five years about 26 per minute. In old age the respirations are very slightly accelerated; in children they are quick and often irregular, being momentarily suspended by anything that excites their wonder or close attention.

The *odour of the breath* may attract attention. It may under morbid conditions be fetid, urinous, 'mercurial,' alcoholic, or gangrenous. *See* BREATH, THE.

The condition of the *skin*, whether dry or hot, moist or sweating, and the presence or absence of any eruption, scars, ulcers, or pigmentation, will be duly noted. The presence of *pyrexia* will be exactly ascertained by the use of the clinical thermometer. The condition of the surface may be tested by the hand. The use of the surface-thermometer, in combination with the ordinary clinical instrument, would give us more exact results; but the hand of the skilled observer generally suffices for the purpose. *See* THERMOMETER, CLINICAL.

The condition of the *finger-ends*—clubbing, lividity—must be observed (*see* FINGERS, Clubbing of). Important information as to the previous acute illnesses within the past six months can be obtained by inspecting the nails, a transverse furrow marking the period of defective or arrested nutrition during such illness.

The condition of the *teeth*, *eyes*, especially of the *pupils*, *tongue* and *gums* furnishes us with valuable information. *See* TEETH; EYE; PUPILS; TONGUE; and MOUTH.

The careful superficial inspection of the patient in the manner above sketched will perhaps at once suggest a more minute examination of some one organ or system of organs as the probable seat of disease; and having thus far succeeded in locating the disease, the other organs and functions of the body will of course come under review, but the physician will be more especially inquisitive with regard to organs or functions associated with those

PLATES XV. and XVI.

The anterior line of reflection of the two pleuræ is somewhat variable, for the meeting of the two sacs, though usually placed behind the sternum, may lie quite to the left of the median line. Also the line of reflection of the left pleura may diverge from that of the right as high up as the level of the fifth costal cartilage, or on the other hand the two pleuræ may remain in contact as far down as the ensiform cartilage. The area of pericardium left uncovered by pleura varies in a corresponding manner. The lines indicating the pleural reflections in Plates show the average positions. The inferior line of reflection of the pleura in the mid-lateral line is rather lower on the left (lower border of tenth rib) than on the right side (lower border of ninth rib). Posteriorly the pleura may descend as low as the first lumbar transverse process.

The position occupied by the vermiform process varies considerably, though it will usually be found either as indicated in Plate XVI. or, lying behind the ileum and mesentery, directed upwards and to the left from its origin at the inner and back part of the cæcum.—G. B. MOWER WHITE.

Modified from Luschka by G. Mower White.

Modified from Luschka by G. Mower White

in which disease has been detected. If careful examination fail to reveal any organic lesion sufficient to account for the symptoms present, we may then—but not till then—refer the case to one of those diseases which for a time run their course without manifesting any definite lesion.

2. Nervous System, Physical Examination of.—See p. 1063.

3. Respiratory System, Physical Examination of.—The respiratory system includes the respiratory tract and lungs.

(A) NARES.—The shape of the nose, the narrowing of the anterior nares and the marked naso-labial fold with the mouth partly open would suggest the obstruction of the upper air-passages by enlarged tonsils or adenoids. The condition of the nasal mucous membrane and the character of nasal discharges should also be observed. See NOSE, Examination of; and TONSILS, Diseases of.

(B) LARYNX.—The condition of the larynx and trachea is examined into by listening to the voice, whether husky, altered in tone, or suppressed. Any tenderness or external deformity is ascertained by careful palpation.

By means of the laryngoscope the condition of the epiglottis, larynx, and trachea can be thoroughly explored. See LARYNX, Examination of.

(C) CHEST.—In making an examination of the chest, the physician should follow a methodical routine of inspection, palpation, percussion, auscultation, and occasionally radiography.

(1) Inspection.—The general shape and build of the chest is observed—whether it be the broad, well-formed chest of robust health; or the small, narrow, long chest, with antero-posterior and lateral diameters diminished, costal angle narrow, and ribs oblique and approximated—adapted to small lungs, or sometimes due to chronic obstruction to the entry of air through the upper air-passages. Or the thorax may be unduly expanded, with wide intercostal spaces, straightened ribs, widened costal angle, and deep antero-posterior diameter, to accommodate large lungs. Again, the thorax may be distorted by various kinds of spinal curvature, or as the result of rickets, or from external pressure, as in the depressed lower sternum of shoemakers. Lastly, there may be local flattenings or bulgings. See CHEST, Deformities of.

The movements of the chest are of great importance in diagnosis. We estimate the freedom or otherwise with which air enters the chest during inspiration by the equable expansion of its several parts, or by the immobility or recession of any portion the entry of air into which is retarded or impeded; and this can be accurately done by means of the pneumograph. In cases of general obstruction to entry of air, whether by impediment at the main air-passage or in its entire distribution, there is universal recession of all the soft parts—the supra-clavicular region sinks downwards, the hypo-chondria recede, and the intercostal spaces deepen during the effort to expand the chest against atmospheric pressure. On the other hand, when the difficulty of expansion, whether from intrinsic disease or obstruction of passages, is restricted to one side of the chest or to a portion of one lung, the restrained expansion during inspiration is limited to that portion. Thus from inspection alone we may often form a shrewd guess as to the seat and even the nature of the disease present.

In estimating local alteration of shape, the eye is perhaps more useful than any instrument of measure, and inspection should be made from above as well as from in front and behind. Calipers of various patterns may be used for taking diameters in different directions, and for recording differences of shape on the two sides the *cyrtometer* is very useful. This instrument was originally introduced by Woillez, and consisted of two halves of a jointed whalebone measure, connected by a hinge, which could be adapted accurately to the shape of the chest, and after removal the various curves on the two sides could be traced on paper. The *cyrtometers* now most in use are made of soft metal, two sufficiently long pieces of which are connected by an indiarubber joint or hinge.

Double tape-measures are also used for ascertaining the circumference on the two sides, and by their means the relative expansion during respiration on the two sides can be compared. Various forms of stethometer have been designed for the same purpose. See STETHOMETER.

The vital capacity of the lungs may be very accurately estimated by means of the spirometer. See SPIROMETER.

(2) Palpation.—Palpation is employed in aid of both inspection and percussion.

(a) During preliminary inspection of the chest the position of the heart's apex-beat should be invariably, and as a matter of habit, ascertained, and any deviation from its normal seat, namely, the fifth intercostal space one inch to the sternal side of the left nipple-line, should be noted. The position of a patient during examination should be borne in mind, the effect of posture upon the heart's position varying in different people.

(b) Any local bulging or tumour will naturally be manipulated to ascertain its relation with bone, or soft structure, whether it be solid or soft, oedematous, fluctuating or pulsatile.

(c) In connection with percussion, the trained observer will note differences of resistance, as well as of sound, over diseased areas. Vibration felt along the rib by one hand when its vertebral end is struck by the finger of the other hand has been found to be increased in fluid effusions (Kellock).

(d) Increase or diminution of vocal vibration or fremitus will be noted over any spot of altered resonance, by applying the hand and making the patient utter some resonant words, such as 'ninety-nine.'

Vocal fremitus is increased by consolidation of lung (unless the bronchus be obstructed by growth or otherwise); diminished by much thickening of the pleura, by obstruction to the main bronchus, or by air in the pleura; annulled by fluid in the pleura. In many cases, however, of fluid in the pleura some vibrations are felt, probably communicated from above. The loudness or feebleness of the voice, and also its pitch, must of course be taken into account in estimating fremitus, and corresponding parts on the two sides should always be compared.

Loud, coarse, bronchial rales may cause the chest-walls perceptibly to vibrate, producing *rhonchal fremitus*. Pleuritic friction may likewise be perceptible to the hand applied—*friction-fremitus*. In cases of effusion into the pleural cavity, or in hydatid cysts near the surface, fluctuation may be elicited on palpation.

(3) Percussion.—Percussion is the method of

examination by which we detect the various degrees of resonance of different parts of the chest, depending upon the relative amount of air and solid structure.

It is best to use the fingers for percussing, one finger of the left hand being placed firmly over the point to be percussed, and struck with one or two of the fingers of the right hand, semi-flexed, so that the tips of the fingers fall vertically upon the pleximeter-finger. Percussion should be made from the wrist, not from the elbow; the stroke should, as a rule, be light, and always perfectly even on the two sides; sometimes a heavier stroke may be needed, but, as a rule, far more information is obtained from light than from heavy percussion. In comparing the percussion-note over the two sides of the chest, points exactly corresponding must be taken, and the pleximeter-finger must be placed in a corresponding position; for example, it must not be placed parallel with the ribs on one side and across them on the other.

The sense of touch is very valuable in percussion in estimating *resistance* of the part struck. Dulness, and particularly the hardness and want of resilience over thickened adherent pleura, may thus be readily *felt* by the pleximeter-finger during percussion. This sense of touch should be carefully cultivated, and its deprivation is a great disadvantage in the use of the artificial pleximeters and percussors first introduced by Piorry, although possibly these may be useful for demonstration to a class. The observer should not be content with comparing corresponding points on the two sides of the chest from above downwards, but he should invariably trace any dulness or resonance from either side across the sternum to ascertain the limits of resonance or dulness in this direction. From neglect of this, important information is often missed. The height to which the pulmonary note extends above the clavicle on the two sides should be compared.

Regions of the chest.—For convenience in describing the distribution of signs, both of percussion and auscultation, it is customary to divide the chest into regions. The names employed to distinguish these regions sufficiently define their limits, namely, the supra-clavicular, clavicular, infra- or sub-clavicular, mammary, infra-mammary regions on each side in front; the superior and inferior axillary regions; the supra-spinous, infra-spinous, inter-scapular, and infra-scapular regions on each side posteriorly.

(a) **NORMAL PERCUSSION-SIGNS.**—There is a certain standard degree of resonance over the lungs, only to be duly estimated by experience, which is known as *normal pulmonary resonance*. In certain regions of the chest the pulmonary resonance is naturally lessened or replaced by dulness. Pulmonary resonance should commence $1\frac{1}{2}$ inch above the level of the clavicle. In the clavicular and sub-clavicular regions, on firm percussion, the note should be even on the two sides, as low as the third rib. Below this level, on the *right* side, we still obtain full resonance until we arrive at the fourth space, where in the mammary line the note becomes slightly raised and shortened, becoming dull in the fifth space and downwards to the margin of the cartilages. On very light percussion the pulmonary resonance may be obtained half a space lower; and at least an inch to two inches difference in level may be obtained between the extreme limits of deep expiration and inspiration. In the lateral

(axillary) region the limit of percussion-resonance reaches about an interspace lower. At the sternal margin it is a little higher, from the encroachment of the right side of the heart upon the inferior angle of the lung. Roughly, and for clinical purposes, a line drawn outwards from the base of the xiphoid cartilage may be said to define the upper border of the liver-dulness.

On the *left* side, in the line midway between the sternum and nipple, we already, at the third cartilage, obtain elevation of pitch and shortening of the percussion-note; and at the fourth space dulness, from the underlying heart. Between this (mid-sterno-nipple) line and the sternum, and bounded above by the fourth cartilage and below by the level of the apex-beat, is the normal area of superficial cardiac dulness. In the nipple-line at the corresponding levels¹ some deadening of percussion-note may be obtained, but pulmonary resonance is otherwise clear to the sixth rib; in the lateral axillary region to the seventh. Below the sixth rib in front, and the seventh laterally, gastric resonance is obtained.

Over the *sternum*, percussion is naturally somewhat wooden and resisting, within degrees varying with the condition of the bones. The first piece of the sternum is normally somewhat less resonant than the next two pieces, but it should be, on firm percussion, by no means dull. Below the level of the fourth cartilages the heart and liver cause the note to be dull, although even here a certain degree of resonance is in health communicated from the adjacent right lung.

In the *posterior* regions of the chest the degrees of resonance are almost entirely in accordance with the thickness and character of superjacent tissues. Thus in the scapular and inter-scapular regions increased force of percussion is necessary to elicit pulmonary resonance, while in the lateral and infra-scapular region the percussion-note is full and low-pitched. On the right side this resonance is replaced by dulness below the tenth rib, and deep percussion will elicit a certain impairment of resonance as high as the ninth rib, in the mid-scapular line. On the left side resonance should be good to the extreme base, except that in the posterior axillary line a small and restricted area of dulness may be sometimes made out, corresponding with the position of the spleen.

(b) **MORBID PERCUSSION-SIGNS.**—Modifications in the distribution of percussion-resonance over the chest may be produced either by general or by local causes.

General causes.—Pulmonary vesicular emphysema, by enlarging the lungs and extending their boundaries, causes encroachment of pulmonary resonance over those regions—the præcordial, right infra-mammary, sternal, and right inferior basic—which are normally dull. In congenital smallness of lungs the boundaries of pulmonary resonance are somewhat retracted, so that liver-dulness in front and behind is slightly higher, and heart-dulness more extensive.

Local causes.—One class of these are encroachments of other organs. Enlargement of the heart will cause increased area of præcordial dulness upwards and to

¹ By employing the terms 'lines' and 'levels' to mean the vertical lines and horizontal levels, in connection with definite anatomical points, e.g. mid-scapular, nipple-lines, nipple-, second-, third-, fourth-, &c., rib levels, any portion of chest-surface may be accurately defined.

the left, or upwards and to the right, according as the left or right side of the heart is most affected. Effusion into the pericardium will cause similar dullness, extending upwards towards the manubrium sterni, and to the right beyond the sternum. Retraction of one lung is a frequent cause of extended (uncovered) cardiac dullness. Aneurysmal tumours in connection with the heart or great vessels give rise to dullness, chiefly in the neighbourhood of the sternum above the fourth cartilage, or in one or other inter-scapular region. Enlargement of the liver and spleen will cause them to encroach upon the pulmonary resonance. Effusion into the peritoneum, if extensive, will cause displacement upwards of the abdominal organs and diaphragm, encroaching upon the lower area of pulmonary resonance, and even causing collapse of the lower portion of the lungs, thus giving rise to dullness.

Effusion of fluid into the pleura will give rise to absolute dullness to the level to which the effusion extends upwards. The upper boundary of this dullness, if the lungs be sound, varies slightly with the position of the patient. In order, however, accurately to define the upper margin of dullness from fluid effusion the lightest possible percussion must be employed. In any case of considerable effusion into the pleura the dullness encroaches upon the median line, and towards the opposite side. See PLEURA, Diseases of.

The chief kinds of morbid percussion-signs will now be discussed.

Dullness, hardness, flatness.—These terms are by no means synonymous with regard to percussion-sounds. *Dullness* varies infinitely in degree. Thus over a pleuritic effusion the tonelessness is absolute; and to this degree of completeness of dullness the term *flatness* of percussion-note is sometimes applied. There are but a few other chest-conditions in which such absolute dullness is obtained; for example, extensive pericardial effusions, hydatid tumours, extensive malignant growths invading the lungs and infiltrating the bronchi. In inflammatory consolidation of the lung there is always a certain degree of wooden tone in the percussion-note. In cases of scattered patches, or nodules, of consolidation in the lungs, with air-containing tissue around, the dullness may be only very slight, amounting to a mere shortening of the note with elevation of pitch. In estimating the slight shades of dullness elevation of pitch is the first point to arrest the attention. *Hardness* of percussion, always more or less appreciable with dullness, is associated especially with consolidations of lung overlaid by thickened adherent pleura.

Skodaic resonance.—In all cases of considerable effusion of fluid into the pleura, in which the lung is not completely collapsed, a peculiar high-pitched tympanitic resonance is found at the sterno-clavicular region on the same side. This resonance, called Skodaic resonance, is a very characteristic sign, and has been attributed to relaxation of lung still in contact with the chest-wall. As the effusion advances completely to fill the chest, this resonance becomes replaced by dullness.

When effusion of fluid follows upon pneumothorax, the lung, unless held above by strong adhesions, is already completely collapsed; and above the level of the dullness caused by fluid there is a tympanitic note, caused by free air in the pleura. In this case the level of the fluid in the pleura shifts with every change in the position of the patient.

Whether the effusion be of serum, pus, or blood, the percussion-signs are the same.

Wooden percussion-note is obtained by percussing over thickened pleura with some air-containing tissue beneath. The sense of resistance is marked, the pitch high, and the duration of sound short. This degree of dullness, with increased resistance, is commonly present below the clavicle in cases of phthisis, with thickened pleura, and perhaps small, empty cavities, bounded by hardened lung-tissue.

Amphoric or tubular percussion is the sound elicited by percussing over a superficial empty cavity, connected by adhesions to the chest-wall. The pitch varies with the size of the cavity, but is always somewhat high. The sound can be exactly imitated by percussing the cheek drawn tensely over the teeth, with the mouth slightly open.

Cracked-metal sound, or bruit de pot fêlé, is obtained by sharp percussion over a cavity such as the above. Sudden displacement of air in the cavity will cause the sound, which somewhat resembles that produced by placing the two hands hollowed in apposition, and striking upon the knee. A little secretion in the cavity will facilitate the production of the sound. This physical state may often be appreciated by the touch before the sound can be heard. It is of little clinical value.

Bell-sound is elicited by combined percussion and auscultation, and *when present* is characteristic of a very large thin-walled cavity in immediate contact with the thoracic wall, and is most generally significant of pneumothorax. The stethoscope must be applied over the resonant part of the chest, and at another point within the same area a piece of metal, such as a coin, laid upon the chest, must be smartly struck with a second piece of metal. The auscultator hears a sound of a clear bell-like character within the chest, which is of quite a different quality from that produced by the mere contact of metals. It is essential for the production of this sign that the stethoscope and the struck metal be both within the area of chest-surface corresponding with the air-containing sac of the pleura. If, for instance, either be placed over a point below the level of any fluid effusion present the sound will be lost, to be recovered on altering the position of the patient so as to displace the fluid. By means of this sign, the limits of a pneumothorax may be accurately defined.

Hydatid fremitus is a vibratile sensation, sometimes to be felt on smart percussion over an hydatid effusion. In cases of pyopneumothorax a similar sensation may sometimes be felt, on percussing at the exact level of the surface of the effused liquid.

(4) *Auscultation.*—Auscultation simply means the act of listening; but the art of auscultation implies a great deal more than this, namely, the appreciation of the healthy or morbid conditions which produce the sounds heard on applying the ear to the chest or to other parts. If the ear of the observer be directly applied to the chest or part under observation, auscultation is said to be *immediate*. If some substance or instrument be used as a medium between the ear and the part under observation, *mediate* auscultation is said to be practised. Such an instrument is named a stethoscope. See STETHOSCOPE.

(a) *NORMAL RESPIRATORY SOUNDS.*—If the stethoscope be applied over the trachea of a healthy

person, tubular, blowing, or bronchial respiration is heard—that is, a sound as of air blown to and fro through a tube with moderate velocity; the mechanism of the sound being the entrance and outflow of air-currents through the narrowed glottic aperture of the trachea, producing sonorous vibrations within the tube below. As the stethoscope is passed downwards to the first piece of the sternum, the same sound is still heard, but more distant and muffled. In the upper inter-scapular region, where the great divisions of the bronchi are comparatively superficial, the tracheal sounds may still be indistinctly recognised; but below and to the side of these points these sounds are normally obscured by the vesicular pulmonary sounds, into the production of which they, however, necessarily enter.

The *pulmonary vesicular breathing-sound* is produced by the friction of air entering the air-sacs from the minute bronchioles, and it is supplemented by the condition of what remains of the glottic breath-sound, now infinitely subdivided. During calm breathing, the sound accompanying *inspiration* should be soft and breezy, giving the idea of innumerable similar and associated sounds. In intensity the sound is uniform from commencement to near the end, when it fades without perceptible interval into the expiratory sound. The *expiratory* sound commences at the moment inspiration ceases, being continuous with the inspiratory sound, but it rapidly fades in intensity, ceasing to be audible after the first one-fifth or one-third of the expiratory act. Of the time occupied between the commencement of one inspiration and that of the next, the inspiratory act occupies nearly one-half ($\frac{1}{2}$ ths); the expiratory act occupies the remainder, with the exception of a very brief interval of pause, between the end of expiration and the commencement of the next inspiration. It may be here observed that when the 'expiration' is said to be *prolonged*, it is meant that the expiratory sound is audible through a longer period of the act than natural.

If the respiration be hurried and forced, the inspiratory sound is coarser and louder, and the expiration more audible, these sounds approximating to the *puerile* breathing which is normal to young children.

In health the vesicular breath-sound should be about equally well heard over the front and back of the chest, allowance being made for additional thickness of covering over certain regions.

(b) MORBID RESPIRATORY SOUNDS.—*Puerile, compensatory or supplementary breathing* is characterised by increased loudness of vesicular breath-sound with some prolongation of expiration. Besides being audible over the chest generally in healthy young children, this exaggerated breath-sound may be heard over certain parts of the chest in persons who have some other part disabled or diseased. Thus, with effusion of fluid into one pleura, the respiratory sounds over the opposite lung are exaggerated or puerile. If one apex be diseased, the breath-sound at the other apex is exaggerated. This increased breath-sound to make up for deficient function elsewhere is called *compensatory or supplementary breathing*.

The breath-sound may be *enfeebled* over the whole chest, as in cases of emphysema or thoracic muscular debility. Localised enfeeblement of breath-sound may be due to several causes—(1) local emphysema; (2) adherent and thickened

pleura, as after old pleurisy at the base; (3) blocking of the alveoli by catarrhal products—common in commencing phthisis at one apex; (4) closure of bronchial tubes by plugs of mucus, or from spasm. If the rest of the lungs be free this local enfeeblement is made up for by compensatory breathing on the opposite side, or in other parts of the same lung.

Suppressed breath-sounds signifies removal of lung from the surface by effusion of air or of fluid into the pleura, or occlusion of a main bronchus by compression or morbid growth.

Wavy and jerking respiration are terms characterising a kind of respiration in which the inspiration is either partially or completely interrupted several times. The expiration is rarely thus affected. Waviness of respiration may be due—(1) to an irregular action of the inspiratory muscles, common in nervous people; (2) to cardiac impulse, in which case these interruptions are rhythmic with the heart's pulsation; (3) unequally distributed impairment of the lung-elasticity, for example, in early tubercular deposits. Walshe considered that pleuritic adhesions may have the same effect. It will be seen then that waviness of breath-sound is very commonly independent of any organic change, and requires other signs to render it of any value in diagnosis. Jerking respiration or interrupted breath-sound is more commonly due to organic lesions of the third kind mentioned.

Cogged breath-sound is a somewhat clumsy term applied to a form of interrupted respiration in which the interruptions are very even, three or four to each inspiration. Much importance is attached to the sign by some authors. It appears to be due to obstruction in the smallest bronchioles, either by dryish secretion or small nodules of tubercle, requiring some accumulation of inspiratory force to overcome it. The sounds commonly give place to a bubbling rale.

Harsh respiration with prolongation of expiration implies a want of vesicularity in the sound. While vesicular breath-sound has been compared to the sound produced by the breeze passing through leaf-laden trees, harsh breathing, on the other hand, resembles a similar breeze traversing their naked branch-tops. Some prolongation of the expiratory sound is inseparable from harshness of breath-sound. Harshness of breath-sound by no means implies increased loudness—rather the contrary. Enfeebled respiratory murmur is commonly harsh—always so when due to alveolar obstruction. The meaning of harshness of breath-sound is simply commencing consolidation; it goes with incipient dulness, and is one of the earliest signs of apical disease in consumption. There can be little doubt that its real mechanism depends upon the extinction of the vesicular part of the normal breath-sound, and the better conduction of the glottic sounds, which at peripheral parts of the lung are usually muffled and obscured by the vesicular sounds. The prolongation of the expiration is very characteristic of this early alteration of the respiratory sounds; and it may here be observed, in passing, with regard to morbid breath-sounds, that the expiration is the most important part of the respiratory act to attend to in auscultation.

Divided respiration, usually described as a separate evidence of disease, is really an inseparable factor of harshness of respiration. Instead of the two component sounds, inspiration and expira-

tion, fading imperceptibly into one another, they are more or less distinctly separate, the more so as the more typical bronchial type of breathing is acquired. Deficiency of elasticity is the cause to which the division is usually ascribed; it is, however, a significant feature of glottic breathing.

Bronchial respiration is most typically heard over simple lung-consolidation, as pneumonia at the base or apex. Skoda well describes the sound as acoustically identical with that produced by placing the mouth in the position to pronounce the guttural *ch* (as in *choir* or *christian*), and drawing the breath to and fro. The inspiratory and expiratory sounds are about equal in length, nearly identical in pitch, and distinctly divided from one another. The sound varies in intensity and definition, from the most intense *tubular* or *tracheal* breath-sound to the lower-pitched and more diffuse *blowing respiration* (*diffused bronchial breathing*). Besides hepatisation of lung, this form of respiratory sound may be produced by other condensations of lung, for example, from pressure or by tumours extending from the neighbourhood of a large bronchus to the surface, such as enlarged bronchial glands, mediastinal growths, and aneurysmal tumours. The more diffused blowing sounds are due to less complete consolidation. It is essential that the bronchi be patent, in order that bronchial respiration may be heard; thus, in cases of cancerous growth invading a lung from its root and occluding the bronchi, no respiration is audible. As regards mechanism, however, it can scarcely be maintained that the sound is produced by the passage to and fro of the air in the bronchi of the consolidated lung; for (1) at the period when bronchial breathing is most distinct the lung is immovably fixed by exudation; (2) the play of the chest-wall on the affected side is almost or quite restrained; (3) the air-cells being occupied, there is no reason why air-currents should penetrate the bronchi. Hence it would seem that bronchial respiration is but the glottic breath-sound reverberating through the bronchial tubes, and well conducted to the surface. A remarkable experiment of Bondet and Chauveau strikingly confirms this view. In a horse with hepatisation of the base of one lung and bronchial breath-sound over the part affected, the trachea was incised below the glottis and the wound held widely open; the bronchial breathing immediately disappeared, all respiratory sounds ceasing over this portion of lung, while elsewhere the vesicular breath-sound was unimpaired. A musical reed was now inserted into the wound, and the musical sounds were well conducted over the consolidation, but little audible over the healthy portion of lung.

Cavernous respiration is a breath-sound in which the inspiration and expiration have both a hollow blowing quality. It is to the expiration that the hollow wavering quality characteristic of this breath-sound is especially attached, and, as pointed out by Reginald Thompson, the expiratory sound is lower in pitch than the inspiratory. Cavernous breathing signifies a pulmonary cavity usually phthisical—(1) exceeding in size an unshelled walnut; (2) either empty or at least partially so; and (3) communicating with one or more patent bronchial tubes. Softening of tubercle or caseous pneumonia, pulmonary abscess, or bronchial dilatation of sufficient size, are the most common causes of cavity in the lung. This abnormal sound is formed by—(a) the

passage to and fro of air into a cavity with the respiratory movements; (b) the conduction and modified reinforcement of the glottic respiratory sound within a cavity.

Amphoric breath-sound is a variety of cavernous respiration having the same characters, but on an exaggerated scale: that is, not necessarily exaggerated as regards loudness, but having all the qualities—blowing character and hollowness—intensified. This sound is heard over a large superficial cavity, either in the lung, or in the pleura freely communicating with the lung. Its mechanism is identical with that of cavernous respiration, only that the size of the cavity is large.

(c) **ADVENTITIOUS AUSCULTATORY SIGNS.**—A *r le* or *rhonchus* is a sound produced by impediment to the entry or escape of air within the lungs or bronchial tubes. The impediment may be from narrowing, or secretion within the tubes; from secretion within the alveoli; or from destructive softening or oedema of the lung-tissue. The *r les* that may be audible over the chest are—*sonorous*, *sibilant*, *crepitant*, *sub-crepitant*, *mucous*, *dry crackling*, *moist crackling*, and *cavernous*.

Sonorous and sibilant r les or rhonchi are noises of a snoring or whistling kind, which are produced in the air-passages. They are audible with both inspiration and expiration (or with either), and are for the most part transitory sounds, being temporarily or permanently removed by cough, or in other cases by the relief of the spasm which has occasioned them. They obscure or altogether mask the normal respiratory sounds. Any narrowing of an air-tube will give rise to rhonchus or sibilus according to the degree of narrowing and the size of the tube. Thus, if the larger tubes be affected, and the narrowing not great, the coarser sound is produced. If, on the other hand, the finer tubes be partially occluded, or a larger tube be greatly narrowed, the finer sibilus is caused. Rhonchi are audible throughout the territory of the tubes affected. Thus, if a main bronchus be compressed or narrowed, the sound so occasioned will be heard throughout the lung on that side. Throat-sibilus in croup is conducted all over the chest.

The precise causes of rhonchi are—(1) narrowing of a bronchus from external pressure (uncommon); (2) narrowing from local cicatricial thickening and contraction of the fibrous coat of the tube (uncommon); (3) mucous collections in the tubes giving rise to imperfect plugs which vibrate, causing the musical sounds (very common); and (4) spasmodic contraction of the medium-sized tubes (sibilus in asthma).

Rhonchi signify—(1) bronchial catarrh, or bronchitis, local or general, as the case may be, affecting the larger and medium-sized tubes; (2) tumours pressing upon the trachea or one of the main bronchi; (3) numerous minute bronchial obstructions occasioned by pulmonary miliary tuberculosis; or (4) asthma.

Stridor is a variety of rhonchus, due most generally to pressure of a malignant or aneurysmal tumour upon a main bronchus, and heard chiefly over the corresponding side. It is a coarse, vibrating sound, which, however, the trained ear can readily detect to be of distant origin. Paralysis of the vocal cords will, in some cases, lead to stridor.

Crepitant r le, or *fine, dry crepitation*, is a minute, dry, crackling sound, in which the crackles are infinitely small and even, and occupy chiefly

the latter part of inspiration. The sound has been compared to the crackling of salt upon the fire, or that produced by rubbing a pinch of hair between the fingers close to the ear. Probably the exact mechanism of the sound is the abrupt separation of alveolar surfaces, collapsed by inflammatory or other oedema. But there are difficulties in the way of any present explanation of the sound. There are at least four conditions which will give rise to identically the same sound, as far as the ear can appreciate it—namely (1) incipient pneumonic consolidation (inflamed oedema stage); (2) oedema of the lungs when not excessive, as in certain stages of kidney-disease, in obstructive heart-disease, &c.; (3) mere collapse of lung from disease, crepitant *râle* being often temporarily heard from this cause at the extreme posterior bases, to disappear after a few deep inspirations; and (4) certain cases of oedema of the pleura dependent upon old lung-disease. The fine crepitation of pneumonia is peculiar only in being associated with commencing tubular breath-sound, the consolidation associated with which gives an increased intensity and definition to the crepitant *râle*. When associated with acute febrile symptoms, fine crepitation indicates the congestive stage of acute pneumonia. If seated about the base, the pneumonia is most commonly of the typical croupous or exudative variety. If at the apex, or in patches, the disease may be incipient catarrhal or embolic (pyemic) pneumonia.

Sub-crepitant or muco-crepitant râle is a fine bubbling *râle*, of sharp definition, and well-conducted to the ear, audible principally during inspiration, but in less degree also with expiration. This *râle* is produced in the minute bronchioles and alveoli, by the penetration of air through a thin liquid. A certain amount of lung-condensation is necessary to give sharpness of definition to the sound. Sub-crepitant *râle* is most typically heard in the resolution stage of pneumonia. In the second (secretion) stage of broncho-pneumonia it is also heard. There are many *râle* sounds intermediate between true dry crepitation and the sub-crepitant *râle*, which are fairly described by the general term crepitant *râle*, fine or coarse, according to their size. Many degrees of fineness or coarseness may be distinguished in different parts of the same lung in some pneumonic forms of phthisis, and it will be generally found in any such cases that the *râles* increase in coarseness as we ascend from below upwards.

Dry crackle is the term used to describe a *râle* consisting of three or four distinct small crackles heard during inspiration. The crackles are dry in character, and sharply defined. The inspiratory breath-sound attending this rhonchus is usually feeble and harsh, the expiration harsh and prolonged, but unattended by any *râle*, unless it be some sibilus. Dry crackling most commonly signifies commencing softening of 'tubercular' deposits, and the sound may be most frequently recognised in the sub-clavicular region, where this condition is most often found uncomplicated by conditions depending upon other stages of the disease.

Moist crackle, or humid clicking râle, consists of a few crackles, heard during the latter part of inspiration and the commencement of expiration, sharply defined, sometimes metallic in quality. The crackles vary in size and in the degree of liquidness, as must be the case from the mechanism

by which they are produced. For this *râle* is significant of liquefaction of tubercular or caseous pneumonic nodules in communication with bronchial tubes; and as such adjacent softenings coalesce and increase in size, the crackles become larger, until they develop into the *gurgling* or *cavernous râle*. The moist crackle may be associated with other *râles*, since a softening caseous nodule is often surrounded by congested pulmonary tissue or pneumonia, giving rise to fine crepitant or sub-crepitant sounds. As a rule, the breath-sound is more or less masked by the crackling *râle*.

Cavernous and gurgling râles are but larger and more liquid *râles*, produced in a cavity or cavities of moderate dimensions.

Metallic tinkling râle requires for its development a large empty cavity in which it may be produced—(1) by the bursting of one or more air-bubbles through viscid contents; (2) by the impingement of a drop of secretion against the cavern-wall; or (3) by a bubbling *râle* produced in a bronchus near the cavity, and freely communicating with it. In either case the large empty cavity, necessarily near the surface, resonates and re-echoes the sounds, and gives them their peculiar metallic quality, which has been likened to that produced by a pin dropping into a large empty bottle. Metallic tinkling is by no means solely significant of pleuritic cavity, as was supposed by Laennec; it may be most typically heard over a large dense-walled empty pulmonary cavern.

Metallic echo is sometimes confounded with metallic tinkle, with which it is often associated, and, indeed, of which it may be said to form a part. It is really not a *râle* at all, however, but an echo in a large cavity, produced—(1) by air-vibrations caused by cough; (2) by vibrations on the surface of fluid with a large air-space above; or (3) by vocal vibrations reaching through the cavity after true voice-sound has died away.

Hippocratic succussion-sound is the splashing sound heard in a pleura containing both air and fluid, on shaking the patient somewhat vigorously, while the ear is applied to the chest-surface.

Cough-sounds.—A *cavernous splash-sound* may frequently be heard on listening over a cavity, and causing the patient to cough, the forcible entry of air into the cavity in itself largely contributing to the sound, and setting up gurgling and splashing *râles* by the disturbance of contained fluids.

Cough-sounds require no explanation, but they should be invariably tested in chest-examination. Crepitant sounds are often developed after a cough, which are not to be heard either on ordinary or deep inspiration without it. *Cavities* which are not in free communication with bronchial tubes may yield no characteristic breath-sounds; but the forcible propulsion of air into them at the moment of chest-compression with closed glottis elicits at once a characteristic localised succussion-sound, attended by more or less coarse gurgling *râle*.

Voice-sounds.—In the ordinary healthy spongy condition of lung, the voice-sounds are heard but distantly and imperfectly, save in certain parts of the chest in the neighbourhood of the trachea and its bifurcation—that is, in the upper sternal and the upper interscapular regions, where the sounds are better conducted.

Bronchophony.—At any portion of the chest where there is consolidation of lung, in association with patent air-tubes, the voice-sound is heard

loudly, as though produced near or close, under the stethoscope. Although loudly heard, the sound appears to pass away from under the stethoscope. Any solid medium of conduction between a large bronchus and the stethoscope will give rise to bronchophony, whether by super-position, or by the portion of bronchial tree concerned being embedded in solid lung, as in lobar pneumonia, of which the sound is most typical. If, however, between the conducting medium and the larynx the bronchial channel be occluded, bronchophony is no longer heard, the voice-sounds being enfeebled or annulled.

Pectoriloquy.—If, on the other hand, a cavity be present beneath the spot auscultated, and in free communication with a bronchus, the voice-sound appears to be concentrated at the end of the stethoscope, and to pass *through* the instrument direct to the ear, with exaggerated and even painful distinctness. It is rather the *noise* of the voice that we hear in bronchophony, but in pectoriloquy the sounds are most distinctly *articulated*. This distinction is even better appreciated by listening to a whisper, which under bronchophonic conditions is merely a conducted hissing sound, while in pectoriloquy each syllable penetrates distinctly to the ear. Pectoriloquy may, however, be clearly, although not exactly, imitated by consolidated lung in the neighbourhood of a large bronchus. Hence the diagnosis of a cavity near the root of the lung requires much caution.

Egophony.—Egophony is a form of modified bronchophony in which the voice-sound, conducted through condensed lung, has further to penetrate a thin layer of fluid in which the coarser vibrations are lost, a certain quavering nasal quality being given to the sound that reaches the ear. It is significant of effusion into the pleura. The sound is only to be heard near the upper limits of the effusion, where the layer of fluid is thin.

With regard to the mechanism of these three sounds—bronchophony, pectoriloquy, and egophony—there can be no dispute about their being glottic sounds. In *bronchophony* they are conducted through subdividing tubes of increasing fineness enveloped in solid tissue; hence the sounds, although loudly heard, are not well defined, being largely converted into the coarser vibrations perceptible to palpation as *fremitus*. In *pectoriloquy*, on the other hand, the glottic sounds are conducted through tubes which, after one or two divisions, terminate in a resonating cavity; hence the vocal vibrations are concentrated and conducted with intensity to the ear as through a speaking-tube. Finally, in *egophony* one may suppose the bleating character of the sound to be due to secondary, and to a certain extent disturbing vibrations in the fluid medium through which the sounds are conveyed. In *egophony* one may commonly note a lisp or whisper-sound in addition to the voice-sound, and better conducted than the voice-sound. And it has been affirmed by Bacelli that in cases of *serous* effusion into the pleura the whisper is heard well conducted with distinct articulation—*pectoriloquie aphonique*—through the thickness of the fluid, whereas in *purulent* effusion such whisper is not conducted. This statement will be found to apply, however, only in certain cases. The whisper may sometimes be heard well conducted through purulent fluid.

The voice-sounds are *weakened* or wholly *extin-*

guished by conditions which: (*a*) shut off the main bronchi from the part auscultated, as in malignant growths invading the bronchus at the root of the lung; (*b*) separate the lung-surface from the thoracic wall, as in pleuritic effusions, œdematous thickening of pleura, &c. Here, however, we must make exception in certain cases, in which pectoriloquie aphonique is heard. In (*c*) rarefaction of the lung by emphysema the voice-sound is enfeebled; and in (*d*) pneumothorax it is either much enfeebled or annulled. In cases of pneumothorax, however, a faint *metallic echo* may often be heard with, or rather after, the voice-sound. This echo has probably a precisely analogous mechanism to ægophony, save that the medium of secondary conduction is air instead of fluid, and hence the conduction is less distinct.

Autophony.—On listening over a superficial cavity with condensed lung-tissue around, the voice of the auscultator—for example, when requesting the patient to cough or to speak—will be noticed by himself to be intensified. The term *autophony* is applied to this increased resonance, which is a sign of little clinical value.

Pleural sounds.—The sounds originating in diseased conditions of pleura are commonly included under the general term ‘friction-sounds’—a term, however, very inadequate to describe the varieties.

The *pleuritic rub* or *dry friction* is a wavy or uneven rubbing sound heard close under the ear with both inspiration and expiration, but chiefly with the former, unmoved by cough, and usually attended by pleuritic pain. We may often fail to obtain this sound, through the patient involuntarily restraining the movement of the affected side on account of the pain. A deep inspiration must, therefore, be always called for. In well-marked cases the friction is very loud and leathery, and may be perceptible to the hand applied—*friction-fremitus*.

Pleural creaking is a sound that may be sometimes distinguished over a portion of the chest, when the pleuræ are densely thickened and adherent.

Moist or spongy friction is most difficult to distinguish from fine moist crepitation. It is heard almost entirely at the end of deep inspiration, and closely resembles the crepitation of a moist sponge. The sound is due to the pleura being adherent by moist, recent lymph, as in the early stage of adhesive pleurisy in pleuro-pneumonia.

In cases of œdema of the pleura a fine crepitating inspiratory sound or *pleural crepitus* may be heard, which it is impossible to distinguish from a pulmonary sound. The diagnosis must rest upon the very superficial character of the sound, and its being unchanged by cough; also upon its being associated with deficient breathing without tubular quality, and with lessened vocal fremitus. It is an inspiratory not an expiratory sound, being engendered by the pulling out of the spongy œdematous tissue during inspiration.

(5) *Radiography.*—Examination of the chest by radiography has of late years been increasingly made use of. See RÖNTGEN RAYS.

4. *Circulatory System, Physical Examination of.*—The condition of the heart and circulation may be investigated with great exactness, chiefly by palpation, percussion, and auscultation.

PULSE.—The pulse gives us very important information respecting the state of the circulation.

For a full description of the pulse and its different characters in disease, *see* PULSE, THE; and SPHYGMOGRAPH.

HEART.—(a) **Inspection.**—In health and during quietude the cardiac impulse is barely perceptible. Under excitement, however, a throbbing impulse may be noticed over the præcordia and left epigastrium. In cases of great hypertrophy and dilatation of the heart, especially in children, the præcordial region may be obviously bulged. The impulse of the heart may be observed to be diffused over an increased area, between the nipple-line and sternum, in cases of hypertrophy and dilatation. In cases of dilated hypertrophy of the right ventricle, or in displacement downwards of the heart in emphysema, the impulse is very perceptible at the epigastrium to the left of the ensiform cartilage. A diffused undulating impulse may be observed in some cases of pericardial effusion and in adherent pericardium. The heart is often uncovered, and its impulse revealed on one side or the other by retraction of the lung in contractile or wasting pulmonary diseases.

(b) **Palpation.**—The position of the heart's apex should first be ascertained; and the area, force, and rhythm of the cardiac pulsations, and the presence or absence of thrill or other adventitious palpation-signs, should next be noted.

Normally the heart, enclosed in its own pericardial sac, is situated in the anterior and central part of the thoracic cavity, immediately above the diaphragm. Its position may be roughly defined as within the area bounded above by a line drawn across the sternum at the level of the lower border of the second cartilages; on the left by a vertical line passing just within the left nipple; and on the right by a similar line drawn at one-third of the distance between the border of the sternum and the right nipple-line. A slanting line from the base of the ensiform cartilage to the upper border of the sixth rib in the left nipple-line defines the lower border of the heart. Behind this area the heart lies obliquely, its base directed upwards to the right and backwards, its apex to the left downwards and forwards. The organ, moreover, is so placed that the right auricle and ventricle occupy nearly the whole anterior surface; the left auricle and ventricle the posterior and left surface.

The apex of the heart in the adult impinges in the fifth interspace, one inch within the left nipple-line. The aortic and pulmonary valves correspond with the upper border of the third left cartilage at its junction with the sternum, the aortic being on the right of and a little lower than the pulmonary. A line drawn from the middle of the third left cartilage as it joins the sternum, to the upper border of the fifth right cartilage at the sternal margin, would correspond with the mitral valve superficially and above, the tricuspid more deeply and below.

An *altered* position of the apex-beat may arise from congenital displacement of the organ, for example, from transposition of viscera. It may arise from enlargement of the organ by hypertrophy or dilatation, affecting its right or left cavities; or from displacement of the organ, for instance, *downwards*, by emphysema, aneurysm, or tumour; *aside*, by pleuritic effusion, malignant disease, or contraction of lung; *upwards*, by abdominal distension, disease in the abdomen, or contraction of lung.

In continuance of palpation, the condition of the

arteries and veins at the root of the neck must be observed: whether the arteries unduly pulsate, or the veins on one side or both remain full or pulsate.

(c) **Percussion.**—The præcordial dullness may be enlarged by retraction of the margin of one or both lungs; by effusion of fluid into the pericardium; or by enlargement of the heart itself, either general or restricted to one or more of its divisions. The cardiac dullness may be diminished or obscured by enlargement of the lungs enveloping it, or by gas in the pericardial sac.

(d) **Auscultation.**—By the simultaneous contraction of the ventricles, the closure of the mitral and tricuspid valves, and the impact of the apex of the left ventricle against the ribs, a single sound is produced, the first sound of the heart. The sudden tense closure of the mitral valve is the principal cause of this sound. The first sound is closely followed by the second sound, which is more tapping in quality, and corresponds with the closure of the aortic and pulmonary valves. Then comes the diastolic pause, which may be said to equal in duration that of the two sounds. The first sound is most loudly heard at the apex, the second at the base of the heart.

The sounds of the heart are subject to considerable variations under varied general conditions of health and disease.

(1) In general debility, anæmia, and wasting diseases, the tendency is for the first and second sounds to approximate to each other in character. As the ventricular wall becomes atrophic or ill-nourished the first sound becomes more purely valvular, and at the same time more feeble and tapping, approaching thus in character to the second sound. Sometimes in cases of anæmia the first sound is peculiarly ringing and hollow in character.

(2) In chronic Bright's disease, with thickened vessels and hypertrophied ventricles, the first sound is peculiarly muffled and indistinct, compared with the recognisable force of the beat.

(3) The rhythm of the heart's sounds may be greatly changed: (a) The first or second, or both first and second sounds, may be reduplicated. This may occur as a temporary phenomenon in apparent health, but it is more commonly traceable to increased resistance either in the pulmonary or systemic circulation. (b) Excessive rapidity of action. (c) Irregularity in time and force of beats. (d) Intermittent action. These several phenomena may be significant of disease of the heart itself; or, as is frequently the case, they may be due to functional disturbance through the nervous apparatus, from dyspepsia, or from excessive smoking, tea-drinking, or venery.

A *murmur* or *bruit* is an abnormal sound, invariably of a blowing character, which may more or less replace or obscure the normal heart's sound. Either of the sounds of the heart may be replaced or attended by a murmur; and in auscultation, with regard to prognosis, it is much more important to note whether a murmur wholly or only partially replaces the normal sound—that is, whether the function of the valve be wholly or only partially disabled—than to be guided by mere loudness of *bruit*. The first sound at the apex may be preceded, or, very rarely, succeeded by a murmur. For a description of these murmurs, and of morbid pericardial sounds, *see* HEART, VALVES AND ORIFICES OF, Diseases of; HEART, Functional Disorders of; and PERICARDIUM, Diseases of.

5. Mediastinum, Physical Examination of.—Having examined the thorax with regard specially to the great organs, the lungs and heart, contained within it, the mediastinal region should next be explored, both anteriorly and posteriorly.

NORMAL SIGNS.—The anterior mediastinal region, clinically speaking, corresponds with those portions of the sternum not underlain by lung, namely, the manubrium and the left half of the body, extending from the fourth cartilage downwards.

The lungs normally approximate beneath the upper portion of the second part of the sternum; from that point to the lower border of the fourth cartilages hiding the subjacent parts. In the triangular space behind the *upper* sternum, with its apex at the lower border of the manubrium and its base at the episternal notch, lie the inferior extremity of the trachea, covered by the left innominate vein, the summit of the arch of the aorta, and a prolongation of the pericardial sac, with connective tissue, and a few small lymphatic glands. The summit of the arch of the aorta corresponds with the level of the upper border of the second rib-cartilage.

Imperfect percussion-dulness and modified bronchial respiration, with weakly conducted heart-sounds, are usually present over this region. On deeply depressing the finger behind the sternum in the episternal notch, a slight pulsation, communicated from the aorta—which vessel, however, the fingers cannot reach—is felt. The lower region of mediastinal dulness, that is, below the level of the fourth cartilage, is continuous on the left of the sternum with the heart's dulness, and, indeed, corresponds with the præcordial region.

MORBID SIGNS.—The *upper* mediastinal dulness may be replaced by resonance—(1) from enlargement of the lungs in emphysema; (2) in cases of contraction of the upper part of one lung, enlargement of the opposite lung wholly occupying the lateral region, and effacing the normal mediastinal dulness. The limits of normal mediastinal dulness may be *extended*, from displacement of the anterior margin of the lungs—(1) by dilatation or aneurysm of the aorta; (2) by mediastinal abscess; (3) by simple enlargement of the mediastinal or thymus glands; or (4) by morbid growth—cancer, or lymphoma. (For the diagnosis between these several conditions, see AORTA, Diseases of; and MEDIASTINUM, Diseases of.) It must be borne in mind that considerably increased dulness, and even prominence, may be due to intrinsic disease of the sternal bone, or to thickening from periostitis.

Alterations in the boundaries of the *lower* region of mediastinal dulness are most often due to enlargement of the heart, or dilated pericardium. Aneurysm of the aorta or the heart, or a growth extending forwards, between the heart and the lung, from the posterior mediastinum, are the other causes of increased inferior mediastinal dulness.

Posteriorly there is no inter-pulmonary space apparent save that occupied by the spinal column. But in disease, and especially in tumour, whether aneurysmal or of the nature of morbid growth affecting the root of the lungs (see BRONCHIAL GLANDS, Diseases of), the posterior mediastinal dulness involves the right or left interscapular region, as the case may be.

The bifurcation of the trachea corresponds with the body of the fourth dorsal vertebra. The

descending portion of the arch of the aorta corresponds with the left side of the third dorsal vertebra.

6. Abdomen, Physical Examination of.—The abdomen is that portion of the body included between the diaphragm above and the brim of the true pelvis below; and is usually divided, for convenience of clinical reference, into regions. Two horizontal lines drawn at the level of the ninth ribs, and the highest points of the crests of the ilia respectively, and intersected by vertical lines drawn from the eighth rib on each side down to the middle of Poupart's ligament, divide the abdomen into nine regions, namely, epigastric, umbilical, and hypogastric in the middle; and hypochondriac, lumbar, and iliac on each side, from above downwards.

(a) **Inspection.**—When examining a case of abdominal disease the position naturally assumed by the patient should be noticed: whether it be indifferent; or dorsal with the knees drawn up—a position very characteristic of peritonitis; or lateral, with the thighs flexed and the body bent, as in renal or hepatic colic. Sometimes in cases of colic, especially lead-colic, the patient lies on his belly with the arms compressing the part. Frequent changes of posture are also characteristic of colic rather than of peritoneal inflammation. The general size, shape, tenseness, flaccidity, or retraction of the abdomen will be next observed. Any alteration from perfect symmetry will be noted, with the region of any swelling. The superficial veins of the abdomen may be enlarged, the internal mammary from above meeting the superficial and deep epigastrics, to secure collateral circulation between the superior and inferior cavae, when either is from any cause compressed or occluded.

(b) **Palpation.**—On placing the hand over the abdomen for the purpose of palpation, the rigidity or otherwise of the muscles, especially of the recti, will be noticed; and the observer will be careful to note whether the muscle becomes contracted during manipulation, or was from the first unduly tense. The muscles of the abdominal walls are rigid, as a rule, in all inflammatory conditions of the peritoneum. In local peritonitis, and over special organs or tissues which are painful, the muscles are also tense; thus it is not uncommon to find one rectus notably more rigid than its fellow.

In order properly to examine the abdomen by palpation, it is necessary to place the patient flat on his back, on a slightly inclined plane, with a round pillow placed under the head, so as to flex the chin upon the sternum. The thighs should be similarly flexed upon the pelvis by means of a second incline, on which the legs should rest, or by placing one pillow beneath the thighs and two pillows beneath the legs. In this manner the muscles of the abdomen will be rendered as lax as possible. The patient should further be held in conversation, or told to breathe deeply, but without effort, in order that he may not keep his diaphragm fixed. It is often a good plan, when other efforts fail to prevent the patient from keeping his diaphragm fixed, to make him go on counting 'one,' 'two,' 'three,' up to as high a number as he can possibly reach without drawing breath. In this manner we get the diaphragm thoroughly relaxed; and by keeping the hand on the abdomen,

deep palpation can be effected at any period of the counting most suitable for the purpose. The observer should be comfortably placed at about the same level as his patient. The whole hand, previously warmed, should be evenly applied to the surface, and the fingers then depressed in different directions as the hand is smoothly conveyed to different regions. If the patient be poked about with the ends of the fingers by the physician stooping over him, he is either tickled or hurt, his muscles contract, and proper examination is impossible.

It is sometimes useful to make the patient change his position first to one side, then to the other. This method is particularly to be adopted in examining tumours which are movable, such as floating kidneys, some uterine tumours, and aneurysmal sacs. In the case of tumours lying over the aorta, it may be impossible, without adopting this plan, to be sure whether the pulsation felt over them is communicated or intrinsic.

It is sometimes doubtful whether a tumour is situated within the rectus muscle, or in the abdomen beneath it. By keeping the hand over the tumour and making the patient raise himself half to the sitting posture, so as to cause the recti to start forward in contraction, this point can be cleared up.

The temperature of the surface of the abdomen to the hand applied, and to the surface thermometer, may be distinctly raised above that of the general surface in peritonitis.

It is often difficult to estimate the true degree and nature of pain in the abdomen caused by pressure. In hyperæsthesia of the surface the slightest pressure causes suffering; while deep, even palpation gives little inconvenience. If the surface be pinched up the pain is acute. Pain in the abdominal muscles is less acute, and is intensified by bringing these into action. The pain of peritonitis is superficial in so far as it is commonly associated with hyperæsthesia of surface; but gentle, steady pressure is acutely painful, and deep palpation intolerable. The pain of peritonitis may, with the disease, be general or local. There is often some difficulty in differentiating the pain of localised hyperæsthesia—hysterical pains as they are called—from those of inflammatory origin or from tenderness of organs. By holding the patient persistently in conversation respecting symptoms associated altogether with another part, as minute inquiries about headache, cough, &c., and thus keeping off attention while the hand is steadily compressing the supposed painful parts, all doubts can be removed. In neuralgic and hysterical pains simulating peritonitis, the tenderness extends beyond the confines of the peritoneum.

Abdominal organs may be tender to palpation.

Fluctuation.—Fluctuation is an important sign of the presence of fluid in the abdomen, whether the fluid be free in the peritoneum or enclosed in a sac. It may be obtained by placing one hand lightly on the abdomen, while the fingers of the other hand smartly tap over another part, when a fluid wave will be felt to impinge against the applied hand. In certain tense conditions of the abdomen, a deceptive sense of fluctuation may be obtained from the vibrations of the abdominal walls. To prevent this fallacy the hand of a bystander should be applied edgewise on the abdomen, midway between the two hands of the observer, so as to check superficial vibrations.

Hydatid fremitus.—This is a kind of tense fluctuation appreciable by the pleximeter-finger on sharp percussion over certain cysts, more particularly hydatid cysts. See ENTOZOA, p. 461.

(c) and (d) **Percussion and Auscultation.**—Percussion and auscultation of the abdomen are adopted in accordance with the methods already described. The distribution of dullness and resonance, varying or not with the position of the patient, affords important evidence respecting fluid collections, whether peritoneal or encysted. See ABDOMEN, Diseases of; and ASCITES.

By auscultation friction-sounds may be heard over the seat of peritonitis; vascular, aneurysmal, and placental bruits; or the sounds of the foetal heart may be detected.

PHYSICAL EXAMINATION OF THE LIVER.—In the right mammary line the liver underlies the region from the fifth rib to the costal margin: in the median line from the base of the xiphoid cartilage to an inch and a half below that level. The left extremity of the liver lies just within and behind the apex of the heart. It may, then, be roughly said that a horizontal line drawn from the base of the xiphoid cartilage to the right side of the chest and to the apex of the heart, and a second line slanting from within the apex-beat to the right costal margin in the nipple-line, would mark the site of the liver. It has already been observed how this surface is partially covered above by lung. In health the margin of the liver becomes lost to palpation beneath the cartilages in the right nipple-line. Its upper margin may be defined, as already shown, by deep percussion, its lower margin by very light percussion.

Displacements.—The liver may be lowered in position by certain thoracic conditions, such as emphysema, fluid in the pleura or pericardium, thoracic tumours, or compression by tight-lacing. When the liver is thus lowered, it is somewhat anteverted; and in lax conditions of the abdomen its lower margin may be covered by a coil of intestine, thus requiring somewhat deep palpation in tracing it.

The liver may be raised by contractile thoracic diseases, especially on the right side, so that its margin recedes considerably within the costal margin. In cases of doubt as to whether extension of dullness upwards be liver or lung consolidation, the observer must notice whether the level be shifted by respiratory movements. When the abdomen is distended from any cause, the liver is pushed upwards; and in this case, and also in many instances where the liver is drawn upwards, it becomes also tilted somewhat backwards, so that but little more than the margin presents anteriorly. In this condition there may be but little, if any, liver-dullness discoverable anteriorly, and it may erroneously be concluded that the liver is much diminished in size. In these cases, however, the posterior dullness of the liver is increased in the right lower thoracic region. In cases of enlargement of the liver, therefore, the upper margin must be accurately defined, to see if there be extension upwards, and whether that extension be even or uneven. The lower margin must be traced by palpation; the mobility of the organ with respiration estimated; its hardness, softness, sharpness, evenness, or distortion ascertained; and whether it be free or connected with other parts—for example, the spleen, or an abdominal tumour.

The lower margin of the liver, when the organ is enlarged or depressed, very frequently cannot be defined by percussion, being overlapped by intestines. For instance, in cases of lax abdominal arietes, with moderate fluid effusion in the peritoneum, the intestines float up and press between the margin of the liver and the surface. Greatly diminished or absent liver-dullness may be observed in cases of perforation of the bowel, and in cases of paralytic distension of the bowel in acute enteritis. In other cases the front surface may be indurated, and the margin thus incurvated to certain extent and covered by intestines. The surface must be felt—whether smooth, or rough, or nodulated. The *consistence* must be estimated by palpation—whether hard or soft, or fluctuating at any part. See LIVER, Enlargements of.

The gall-bladder cannot be felt unless it be distended, when it presents as a rounded tumour attached to the margin of the liver in the right nipple-line. See GALL-BLADDER AND GALL-DUCTS, Diseases of.

PHYSICAL EXAMINATION OF THE SPLEEN.—Formally, splenic dullness may be ascertained on light percussion in an area on the left side extending from the ninth to the eleventh ribs, and between the mid-axillary and mid-scapular lines. The shape of the splenic dullness is oval in the slant of the ribs.

In moderate *enlargement* the splenic dullness is increased in all directions; and on placing the hand deeply in the left flank, close under the ribs, the organ may be felt to descend upon it during inspiration. As the organ still enlarges it comes forwards and downwards, raising the apex-beat of the heart, occupying the region in front of the scapular line and below the level of the apex-beat, and projecting downwards beneath the costal margin into the abdomen. As the organ still further enlarges, the anterior margin curves forwards, forming nearly a right angle with the costal margin. It is usually sharply defined, and may extend forwards to the median line, and downwards to the pelvis. The posterior margin of the enlarged spleen is also, in such cases of great enlargement, to be felt thick and rounded immediately in front of the quadratus muscle. An enlarged spleen extending into the abdomen is superficial in its entire area; its anterior and posterior borders are well defined; and it can usually be moved between the two hands forwards and backwards. The notch may be commonly felt. The surface may be quite even or nodulated. Sometimes on auscultation a bruit may be audible over an enlarged spleen. Friction-sound may also sometimes be heard. Certain alterations in the constitution of the blood and in the temperature of the body are intimately associated with diseases of the spleen, and the examination of these conditions forms an important item in their diagnosis.

Diminution in the size of the spleen cannot be accurately estimated, and is of little clinical moment.

PHYSICAL EXAMINATION OF THE KIDNEYS.—The kidneys, when of normal dimensions, cannot, as a rule, be felt, especially in fat people, or when the abdomen is enlarged. They lie one on either side near the spinal column, between the level of the spinous process of the eleventh dorsal and of the second lumbar vertebræ, and in the mid-line between these spinous processes and the outer

margin of the flank. Embedded in fat, they rest on the lumbar muscles. The right kidney is overlain in part by the liver, colon, and intestines; the left by the stomach, colon, and intestines; the left kidney is half an inch higher than the right.

In order to feel for the kidney, the patient should be placed in the position for abdominal examination. The observer, standing on the side opposite to that of the kidney under examination, then places one hand along the mid-flank behind, immediately below the last rib; the other hand should rest upon the corresponding part of the abdomen in front, firmly depressing and manipulating deeply, so as to bring the site of the kidney between the phalangeal portions of the two hands. At the same time the patient should be made to inspire and expire deeply; and it is during the stage of moderately deep expiration that the organ will usually be felt.

Tenderness of the kidney, if present, may thus be estimated with certainty. Undue rigidity of the muscles on one side may be observed.

If the kidney be *uniformly enlarged* it simply extends downwards, and comes more readily under observation. In great enlargement of the kidney, as in cancerous tumour, or of its pelvis, as in pyelitis, the organ forms a tumour occupying the flank, and coming forwards from behind the colon towards the front of the abdomen. Such a tumour is more or less pyramidal or rounded in form, with a distinct band of resonance corresponding with the superior flexure of the colon extending across it. The tumour may be solid or fluctuating, according to its nature. Renal tumours are most common on the left side. The pelvis of the kidney, except when considerably dilated, does not come under palpation. See KIDNEYS, Diseases of.

Movable kidneys.—The mobility of the kidneys varies much, from mere laxness to complete dislocation. See KIDNEYS, Malpositions of.

The examination of the urine forms the most important part of the physical diagnosis of kidney-diseases. See URINE, Morbid Conditions of.

PHYSICAL EXAMINATION OF THE PANCREAS.—In thin subjects with retracted abdomen, the head of the pancreas may be felt as a small, somewhat angular, tumour to the right of the median line, above the level of the umbilicus—in the region, in fact, of the pylorus, with thickening of which it may readily be confounded.

Cancerous enlargement of the pancreas extends forwards, in or near the middle line, above the umbilicus, presenting a tumour difficult to diagnose. See PANCREAS, Diseases of.

PHYSICAL EXAMINATION OF OTHER ABDOMINAL VISCERA.—Diseases of the *stomach* and *intestines* yield their proper signs, requiring no separate description here. Tumours of the *omentum* have to be distinguished, by the method of exclusion, from affections of the solid organs of the abdomen.

The *pelvic organs*—uterus, and ovaries, and bladder, under certain conditions of enlargement—present themselves for diagnosis as abdominal tumours.

When distended, the *bladder* gives rise to a pyramidal area of dullness extending in the median line from the pubes, broadening upwards, towards or even beyond the umbilicus. The tumour is firm but elastic, on palpation tender, and is at once removed by successful catheterisation.

In pregnancy at the fourth month the *uterus* becomes perceptible to deep palpation in the pelvic basin in the pubic region. At and beyond the fifth month a tumour of growing dimensions extends from out of the pelvis towards and beyond the umbilicus. Dulness on percussion extends from the pubes over the whole front of the tumour, while above and in the flanks a resonant intestinal note is obtained. The relations of dulness and resonance are not appreciably changed by position. The tumour is elastic, and in the advanced stages obscurely fluctuating. On deep palpation, an irregular resisting lobulated mass is to be felt; and, on keeping the hand steadily applied, undulating movements, or a distinct shock or jerking movement, may from time to time be felt. On applying the stethoscope with somewhat deep pressure, halfway between umbilicus and pubes and a little on one or other side, the rapid beat of the foetal heart may be distinctly heard, closely resembling the tick of a watch under the pillow. On bringing the stethoscope nearer the inguinal region (usually on the right side), the soft low-pitched placental *souffle*, synchronous with the maternal pulse, is to be heard. Enlargement of the uterus from other causes, especially fibroid and fibro-cystic growths, may lead to abdominal tumours, which are diagnosed by combined vaginal and abdominal examination. See UTERUS, Diseases of.

Ovarian tumours also present in the abdomen, extending upwards from one or other side of the pelvic region, and with a disposition as they extend to become central. They are most commonly cystic, and—especially in the later stages—sometimes present difficulties in diagnosis from pregnancy or peritoneal dropsy. See ABDOMEN, Examination of; ABDOMINAL ANEURYSM; AORTA, Diseases of; OVARIES, Diseases of, and other appropriate headings. R. DOUGLAS POWELL.

PHYSIOGNOMY (*φύσις*, nature; and *γνώμων*, an interpreter).

Physiognomy originally meant the interpretation of the nature of an individual by the light of the indications afforded by his countenance, conformation, and movements; but the term is frequently used for the indications themselves.

PHYSOMETRA (*φύσα*, air; and *μήτρα*, the womb).—A condition in which a collection of gas or air is formed in the uterus. See UTERUS, Diseases of.

PHYTOSIS (*φυτόν*, a plant).—A generic term for plant-formation, applicable to epiphytic, phytiform, or parasitic diseases of the skin, of which there may be enumerated the following species: *Phytosis* or *tinea tonsurans*; *phytosis* or *tinea circinata*; *phytosis favosa* or *favus*; and *phytosis versicolor*. See FAVUS; TINEA TONSURANS; and TINEA VERSICOLOR.

PIA MATER, Diseases of.—See MENINGES, CEREBRAL, Inflammation of.

PIETERMARITZBURG, in Natal.—See SOUTH AFRICA.

PIGEON-BREAST.—A deformity of the chest, in which the ribs are flattened laterally and the sternum thrust forward, so that the chest assumes somewhat the shape of the breast of a pigeon. See CHEST, Deformities of.

PIGMENTARY DISEASES OF THE SKIN.
GENERAL STATEMENTS.—Derangement of the pigmentation of the skin may be in the direction either of excess or of deficiency, and either congenital or acquired. These defects usually occur separately, but may be associated together in the same individual, as in leucoderma and melanoderma.

The special affections of *excessive* pigmentation are Nævus pigmentosus, Lentigo, and Chloasma.

Those of *deficiency* are Albinism and Leucoderma.

PATHOLOGY.—Pigmentation of the skin may be derived either from the colouring-matter of the blood, extravasated or exuded into the tissues, and is then only an exaggeration of a normal process; or from matters introduced into the blood, as bile-pigment producing jaundice; or from without, as arsenic or nitrate of silver; or, again, there may be a local infiltration of the skin, as in tattooing, chrysarobin-inunctions, &c. Except where due to local applications, the pigment is deposited chiefly in the rete mucosum, and almost entirely in the lower layers; it may also be seen in the upper layers of the corium in its passage from the vessels to the rete, to which it is conveyed probably by the branching connective-tissue cells. If these cells atrophy or are absent, the skin of the part is abnormally pale, but the untransferred pigment may be deposited in excess in the surrounding skin, as seen in leucoderma, which is associated with melanoderma. Little is known of the pathological causes of general pigmentation, but disturbed innervation doubtless plays the chief part. Thus the bronzing of Addison's disease is, in all probability, produced by chronic inflammation of the abdominal sympathetic; while the general pigmentation which occasionally follows severe chills, and the disturbed pigment-distribution of leucoderma, which has in many cases followed closely on sun-stroke, must also be regarded as nervous manifestations. Local pigmentation is in the majority of cases the direct consequence of acute or chronic hyperæmia, the blood or its colouring-matter escaping from the vessels and discolouring the tissues. This is especially common on the lower limbs, where the dependent position and frequency of varicose veins favour the exudation; the orange-coloured patches, for instance, seen on the leg being the direct consequence of capillary rupture.

Variations occur in colour, duration, and extent. In colour, pigmentation derived from the colouring-matter of the blood varies from a dull yellow or olive to brown or black. It is of a bright yellow or olive when due to bile, and a slate colour from nitrate of silver. In duration it may be temporary as a sequel of skin-eruption and in jaundice, or permanent as in argyria. In extent, pigmentation may be general as in Addison's disease, hypertrophic cirrhosis of the liver with glycosuria, and acanthosis nigricans (p. 12); in small spots, as in lentigo; or in large patches as in chloasma.

Absence of pigment may also be general as in albinism, or partial as in leucoderma.

ETIOLOGY.—Acquired pigmentation may be idiopathic or symptomatic.

Idiopathic pigmentations comprise those due to local causes, such as irritants, including blisters, sinapisms, friction, pressure, scratching, heat, Röntgen Rays, or exposure to the sun.

Symptomatic pigmentations may be (1) *general*,

as in Addison's disease, Graves's disease, leprosy, syphilis, malaria, cancer, tuberculosis, senile degeneration of the skin, argyria, and arsenical pigmentation. (2) *local*—(a) as a sequela of certain skin-eruptions, such as syphilides, lichen planus, and some forms of urticaria; (b) an accompanying manifestation of certain skin-lesions, such as scleroderma, diffuse or circumscribed, and fibroma; (c) due to parasitic affections, as in tinea cruris, tinea versicolor, erythrasma, and the Pinta disease of Mexico. In these, however, the discoloration is on the skin, or at most only in the superficial layers.

On the legs especially, if varicose veins are present, anything which produces hyperæmia is liable to stain the skin.

1. Nævus Pigmentosus.—**SYNON.**: Pigmentary Mole; *Nævus Pigmentaire*; *Ger. Fleckenmal*.

Moles are congenital structures which may be mere collections of pigment (*nævus spilus* or *congenital lentigo*); or the surface may be uneven and warty (*nævus verrucosus*); or the pigment may be in soft tumours of fat and loose connective tissue (*nævus lipomatodes*); or the tumours may be covered with coarse hair (*nævus pilosus*). They vary infinitely in colour, number, size, and distribution, sometimes occupying a nerve-area. Later in life they sometimes become the seat of melanotic cancer or other malignant neoplasm.

TREATMENT.—Small tumours or hairy moles are best destroyed by electrolysis, both hair and tumour being removed by this method, each hair being separately attacked (*see* DEPILATORIES). Larger tumours where not too large, and when their position renders it advisable, should be removed by the knife or caustics. In elderly people, any active change in a mole should be the signal for instant and complete removal.

2. Lentigo.—**SYNON.**: Freckles; *Ephelides*; *Fr. Lentigo*; *Ger. Sommersprosse*. *See* FRECKLES, p. 560.

Some authors restrict the term 'ephelides' to freckles caused by the sun, reserving the term 'lentigo' for the spots which come in covered parts and are independent of season. Lentigines may be a symptomatic condition, as in xeroderma pigmentosa, and as one manifestation of senile degeneration of the skin. On the other hand, they are occasionally congenital, and are then classed with moles.

3. Chloasma.—Chloasma is a generic term for both patchy and diffuse pigmentation, but is chiefly used for the patchy form.

The patches are well defined, sometimes roundish or oval, but they may be of any shape or size, and any shade from fawn to brown, bronze, or black. When diffuse, the colour is always of deeper hue in some regions than others, namely, the axillæ, nipples, umbilicus, pubes, and genitalia. The causation has been discussed in the general ætiology of pigmentation. The most important variety is *chloasma uterinum* of women who are pregnant, or who suffer from chronic uterine irritation. Its most common positions are the linea alba, nipples, and forehead; but it may come in any part of the face. On the forehead it forms one or more irregular patches, but in other parts it is less defined. It usually fades slowly after parturition, but is occasionally persistent. A similar pigmentation of the face has been observed in abdominal tuberculosis, cirrhosis of the liver, constipation, and cancer of the stomach.

DIAGNOSIS.—Chloasma may be distinguished from discolorations due to vegetable parasites by the latter being on rather than in the skin, except in the surface-layers. If there is any doubt, scrapings of the epidermis, soaked in liquor potassæ and placed under the microscope, will show the fungous elements if the discoloration is due to a parasite.

Accidental or malingering pigmentation can be washed off either with soap and water or with weak chlorinated-lime solution. The deposit in chromidrosis can be readily removed with spirit of chloroform or ether.

PROGNOSIS.—Time generally removes pigmentation due to previous eruptions and that due to pregnancy. The duration and continued activity of the cause are the chief factors in determining the likelihood of the removal of the discoloration.

TREATMENT.—When there are only a few scattered lentigines, superficial electrolysis is very satisfactory, but not when they are numerous and crowded, nor in chloasma. Sometimes discutients are effectual, but in a large proportion of cases their action is only temporary. From a half to 5 grains of corrosive sublimate, but not more than 2 grains to begin with, may be added to a fluid ounce of Almond-emulsion, and this painted on several times a day, or lint wet with the lotion kept on for some hours; and if well borne the stronger solution may be used. Other well-approved applications are acetic acid and sulphur made into a paste, and laid on; citric acid (ʒss to ʒj of water); pure carbolic acid very carefully applied with a brush; or salicylic acid made into a paste with glycerine. These should all be used cautiously over a small surface at a time at first, as occasionally in strongly predisposed persons the pigmentation returns worse than before.

4. Argyria.—Argyria is the term applied to the staining produced by the long-continued administration of nitrate of silver, either internally as a remedy for epilepsy or other diseases, or as a topical application to the throat. The reduced metal is deposited in the rete Malpighii and sweat-glands, and round the hair-roots. It is said that 450 grains is the minimum quantity taken internally which has produced the staining; but it is wise to be well within this limit, as, when once it has commenced to show itself, nothing will stop its further development or remove it afterwards. The parts exposed to light, the face, hands, and visible mucous membranes, are most strongly implicated. The colour is of a bluish-grey, slate, or leaden hue, or it may be almost black. Iodide of potassium in large doses has been recommended, but all treatment is unavailing.

5. Arsenical Pigmentation.—This is due to the deposition of the metal in the skin from prolonged administration of arsenious acid. It is general, but attacks most the parts where diffuse pigmentation is usually most marked. At first it may be recognisable by its sparing the central parts of the hair-follicles, so that on the abdomen there are whitish dots on a yellowish-brown ground, but at a later stage the discoloration is uniform. It may be accompanied by keratosis of the palms, soles, elbows, knees, knuckles, and web of the fingers. When psoriasis has been removed by the administration of arsenic, the site of the psoriasis-patches may be the only parts pigmented. If the drug is stopped, the pigmentation usually fades in the course of time.

6. Albinism.—This disorder of pigmentation is described in a special article. *See* ALBINISM.

7. **Leucodermia.**—SYNON.: *Vitiligo*; *Leucopathia*.

This disease is much more frequent in tropical than in temperate climates. It is a mixed condition of faulty pigment-distribution, but is named from its most conspicuous feature. It is notably symmetrical. Its first stage, though often overlooked, is an increase of pigment in certain regions; in this darker area, a white spot forms and enlarges, driving, so to speak, the pigment before it, so that the borders of the white part are convex, and those of the adjacent over-pigmented part concave. The dark part is sharply defined on the white side, while away from the white area it merges gradually into the normal skin. The number and extent of the white areas vary considerably, but the affection may in course of years affect the whole surface, the white part ever encroaching on the dark; or the excess of pigment may be absorbed. In either case, in some regions, or even over the whole surface, an apparent cure is produced in white races from want of contrast, but the part is really abnormally white, and will no longer tan in the sun.

ÆTIOLOGY.—The affection is certainly more common in dark races, and is generally connected with exposure to the sun, some cases dating from sun-stroke; but it has occurred after severe cold. The neurotic temperament and nerve-depressing influences appear to be favouring conditions. The pathology of the process has been discussed in the general statement.

DIAGNOSIS.—Its striking symmetry, progressive course, and the combination of excess with deficiency of pigment, together with the absence of all symptoms other than the pigmentary anomaly, render the diagnosis of leucodermia easy. The last feature is important, as in India the disease has sometimes been called 'white leprosy.'

PROGNOSIS.—The prospect of cure is bad; spontaneous arrest occurs; but apparent cure by the process previously described is the result to be most desired.

TREATMENT.—This is highly unsatisfactory. General tonic and invigorating treatment offers the best chance of arresting the progress of disease; and, of course, arsenic is recommended by some authors. White areas in a conspicuous position might be slightly stained with walnut-juice to render the contrast less striking.

H. RADCLIFFE CROCKER.

PIGMENTATION.—Abnormal coloration of living tissues, not produced by artificial means. The condition may be due to excess of a pigment which is normally present in the tissue affected, or to the introduction of foreign substances.

Pigment is normally present in the deep layers of the epidermis and in the choroid and retina. The colouring matter is known as 'melanin' and is derived from the blood by the action of the living cells; it does not contain iron (*see* MELANIN). Large amounts of this pigment are found in melanotic tumours. Pigmentation of the skin due to excess of this material is met with after exposure to the sun (freckles; sunburn); in Addison's disease; in irritation of the abdominal sympathetic nerves (pregnancy; tumours); and in the conditions known as melanoderma, acanthosis nigricans, and bronzed diabetes. *See* PIGMENTARY DISEASES OF THE SKIN.

Abnormal forms of pigment may be produced by

destruction of blood-corpuscles, the hæmoglobin breaking down into hæmatoidin, hæmosiderin, and other coloured derivatives. Thus when blood is extravasated into the tissues, the surrounding parts are infiltrated with lymph containing dissolved hæmoglobin, and brown pigment is found deposited in the nearest lymphatic glands (*see* EXTRAVASATION). The series of changes of colour which occurs after a superficial bruise illustrates the resulting pigmentation. Similarly organs become pigmented as a result of chronic congestion or inflammation, owing to the escape of blood-corpuscles which occurs under these circumstances: instances are seen in the 'brown induration' of the lungs which results from the continued mechanical hyperæmia of heart-failure; in the slate-coloured mucosa of the bladder in chronic cystitis, or the 'cut-beard' appearance of the intestine in chronic catarrh; and in the pigmented patches and scars which often remain after chronic lesions of the skin, especially those due to syphilis. The breaking up of blood-corpuscles in the circulation, as in malaria, may lead to deposit of masses of pigment in the liver and spleen.

The so-called pigmentary degeneration of the heart is the result of breaking down of the muscle-substance, brownish granules being found in the fibres chiefly arranged around the nucleus; but it is doubtful whether the dark colour of the heart-muscle produced in this condition can properly be called pigmentation, and is not rather due to concentration of the normally existing pigment in a shrunken organ, as occurs in the liver in cases of starvation.

The staining of the tissues in jaundice is due to absorption of bile-pigment into the general circulation. *See* JAUNDICE.

Various foreign substances may be deposited in living tissues, apart from their artificial introduction, as in tattooing. Thus coal and other forms of dust may be inhaled in respiration and deposited in the lungs, giving rise not only to direct coloration of the tissues, but also to chronic interstitial pneumonia (*see* PNEUMOCONIOSES). Salts of silver taken as remedies over a long period of time produce a bluish discoloration of the skin (argyria) which remains permanently; it is due probably to deposit of reduced silver in the skin. The 'blue line' seen in the gums in cases of lead-poisoning is due to insoluble sulphide of lead formed by the action of sulphuretted hydrogen, given off from decomposing material round the necks of the teeth, upon the lead-salts circulating in the blood. In chronic copper-poisoning a similar line of a greenish tint may be seen.

The growth of the parasitic fungus, *Microsporon furfur*, upon the skin gives rise to brownish patches which may coalesce and cover large areas. The condition is easily distinguished from other causes of pigmentation by microscopical examination of scrapings from the brown areas, in which the fungus is easily recognisable. *See* TINEA VERSICOLOR.

For the discoloration of organs after death, due to the process of decomposition, *see* DEATH, Signs of.

W. CECIL BOSANQUET.

PILES.—A popular name for hæmorrhoids. *See* HÆMORRHOIDS.

PIMPLES.—A popular name for papules. *See* PAPULE.

PINTA.—A term applied to a group of tropical, contagious diseases of the skin, caused by the growth of different fungi. The appearances vary with the species of parasite present.

PISA, in Central Italy.—A rather moist, mild, equable, calm, and relaxing climate. Mean temperature, winter 44° F. East prevailing wind. See CLIMATE, Treatment of Disease by.

PITUITARY BODY.—See ACROMEGALY.

PITYRIASIS (πῑτυρις, bran).—SYNON. : Furfur; Porrigo; Fr. *Pityriasis*; Ger. *Kleingrind*.

Pityriasis is a term indicating the existence of branny exfoliation of the epidermis. In the days of Willan and his followers it was employed to designate a heterogeneous group of skin-diseases exhibiting the one common feature of branny scales. Many members of the group are now recognised to be mild forms of dermatitis. Pityriasis versicolor has become Tinea versicolor. Pityriasis nigra was used by Hebra to designate the pigmentation and scaliness found in chronic pediculosis. Slight degrees of dry eczema, especially seborrhoeic forms, were also called pityriasis, e.g. the pale red patches with small scales often seen in children from using too strong a soap. The form of seborrhoea sicca, called dandriff (p. 362), and the fine silvery scales shed in such abundance by many elderly persons, were both called pityriasis capitis, and it is perhaps advisable to retain the name for this condition. As a generic term it is still used. See PITYRIASIS ROSEA; and PITYRIASIS RUBRA.

H. RADCLIFFE CROCKER.

PITYRIASIS ROSEA.—SYNON. : *Pityriasis Circinata et Maculata*; *Herpes Tonsurans Maculosus* (Hebra).

DEFINITION.—An inflammatory eruption, developing acutely like an exanthem, characterised by the formation of pale red, delicately scaly, roundish or oval patches and circles.

ÆTIOLOGY.—Pityriasis rosea is uncommon, about one in 250 cases of all skin-eruptions. It is more frequent in children, though it may be seen at all ages. It occasionally occurs in more than one member of a family, suggesting a possibility of contagion, but there is no definite proof that the complaint can be so transmitted.

DESCRIPTION.—In a slowly developing case of moderate extent there may be no general symptoms, but in an acute and widespread outbreak, slight febrile and other symptoms of general disturbance may precede the generalisation of the eruption; there may be slight enlargement of the glands behind the sterno-mastoid and under the jaw, and sometimes elsewhere, as well as congestion of the fauces. These symptoms accompany the generalisation of the eruption, but a week or ten days before this there has been a primary patch of the same character as the maculate form about to be described. It is often overlooked by the patient, but may be recognised by its being larger and perhaps more ringed than the more recent ones; after some days others form in the neighbourhood; the abdomen, chest, or side of the neck being the regions usually first affected. From one of these parts the eruption spreads, the old part usually clearing away, leaving slight pigmentation, while fresh patches develop, so that in the course of days or weeks the whole body surface may become in-

volved, and all stages of progression and retrogression may be simultaneously observed in different regions. There are two forms of the eruption, the *maculate* and the *circinate*.

Pityriasis rosea maculata consists of roundish, oval, or irregular pale red patches, from a pin's head to a shilling in size, with well-defined borders, very slightly raised above the surrounding skin, and with the surface more or less covered with very fine delicate scales.

Pityriasis rosea circinata, as its name implies, occurs in circles. These commence as patches, and, as they enlarge, clear in the centre, which is left slightly pigmented, while the border is well defined and slightly scaly. When they meet other patches, gyrate areas are produced. There may be slight itching when the patient is warm. The disease tends to get well spontaneously, lasting from two weeks to two months, occasionally longer.

PATHOLOGY.—The pathology is unknown. The 'Microsporon anomoeon,' described by Vidal, has not been accepted as the cause of the affection, but the commencement in a primary patch which enlarges peripherally, and the generalisation of the eruption after an interval, suggest that the disease is due to an organism which invades the skin from without, and is subsequently absorbed into the circulation.

DIAGNOSIS.—The pale red, slightly scaly, barely elevated patches or circles, covering a wide area, and undergoing spontaneous cure, are the most distinctive features of this disease. It is much less raised, and less scaly, than the early scaly or circinate syphilide; has no scaly crusts, but only delicate branny scales; and is not so red or so raised as psoriasis. It spreads too rapidly and widely for tinea circinata; and there is, of course, no fungus as in trichophyton tonsurans. It is not, like lichen circinatus or seborrhoea corporis, confined to the middle of the back and chest, and is never in papular circles; moreover, while that affection lasts for years if untreated, pityriasis rosea gets well in a few weeks or months.

TREATMENT.—Internal treatment is not required in the majority of cases, but in those which have lasted several months the author has found that salicin in 15-grain doses three times a day produces involution; and there can be no harm in giving it at the commencement in all cases, with a fair chance of shortening the duration. A lotion consisting of liquor carbonis detergens, ʒij to ʒviij of water, is useful in allaying itching, and is perhaps curative. At all events, cases soon get well while using it. If the patient is seen when there are only one or two patches present, these may be painted with tincture of iodine, or vasogen-iodine (10 per cent.) may be rubbed in.

H. RADCLIFFE CROCKER.

PITYRIASIS RUBRA (πῑτυρις, bran; *ruber*, red).—SYNON. : *Dermatitis Exfoliativa*; *Eczema Foliaceum*; Fr. *Herpétides Exfoliatives*; *Erythrodermie Exfoliante*; Ger. *Hautkleie*.

DEFINITION.—An extensive and important natural group of skin-affections, characterised by universal, or almost universal, dermatitis; by marked chronicity; by the severity of the congestion and the intense redness of the parts affected; and by the abundance of desquamation, either in the form of fine branny dust, or of large scales or sheets of epithelium.

The term is not applicable to a somewhat similar

condition, which may be caused by the exanthemata (especially scarlatina, erysipelas, r  theln and measles), or by certain drugs (for example, chloral hydrate, belladonna, quinine, copaiba, and phenazone). See DRUG-ERUPTIONS.

  TIOLOGY.—The causes of pityriasis rubra are very obscure. It occurs more frequently in the male than in the female sex, in the proportion of three to two, or perhaps higher. It is most commonly met with between the ages of forty and sixty years, but has been observed in a child of four months, and in a man of ninety years. It is not hereditary, nor is it contagious; but a condition indistinguishable from pityriasis rubra as regards its objective characters, for a time, prevailed in an epidemic form, especially in the infirmaries and workhouses of the west end of London. Gout, and still more rheumatism, strongly predisposes to its occurrence, either as a primary dermatosis or as an epiphenomenon of other skin-diseases; and the same remark applies to chronic alcoholism and interstitial nephritis in a less degree. Its ‘secondary’ form may supervene upon psoriasis or—in diminishing grade of frequency—upon eczema, lichen ruber, erysipelas, seborrh  a, erythema multiforme, pityriasis rosea, or even artificial dermatitis, for example, from chrysarobin.

The most frequent immediate antecedent of pityriasis rubra is a chill, while the subjects of it are frequently neurotic and intensely susceptible to cold, with other evidences of ill-balanced peripheral circulation. Severe nervous shock and mental strain seem mainly responsible for a certain number of cases.

ANATOMICAL CHARACTERS.—These are in no sense characteristic. They include marked congestion and dilatation of the blood-vessels of the most superficial parts of the skin, and comparatively little of those of the deeper parts; separation of the upper two-thirds from the lower third of the horny layer; thinning of the Malpighian layer over the papill  , with great increase in size and depth of the inter-papillary processes; marked hypertrophy of the papill  , with intense leucocytic infiltration of them, and of the upper layers of the corium. Elacin and collacin are present as in senile skin. In a later stage the whole thickness of the skin is involved, and ultimately a process of sclerosis takes place, with formation of cicatricial tissue, pigmentation, and destruction of sebaceous and sudoriferous glands.

SYMPTOMS.—From the foregoing definition it will be manifest that a large number of maladies present the common characters attributed to pityriasis rubra, the synonym for which (*dermatitis exfoliativa*) is now in habitual use to connote the condition, both in Great Britain and on the Continent.

TYPE I. Secondary pityriasis rubra.—Generalised red and desquamative eruptions secondary to other dermatoses (herp  tides exfoliatives, Bazin).

The diseases upon which this condition may supervene have already been enumerated. In the case of eczema discharge diminishes and small, dry, whitish scales form in increasing numbers. The scaling of psoriasis becomes finer, while the margins of its patches usually become more and more ill-defined, although in one case observed by the writer blebs formed round them. The bull   of pemphigus become flaccid, and resemble the

lesions of pemphigus foliaceus. Gradually from the primarily affected parts the erythrodermia spreads over the whole body surface, which becomes covered with fine branny scales, the feet and soles being the parts most frequently spared. The nails become hypertrophied and claw-like, or may be shed and repeatedly re-formed. The general condition is usually maintained, the appetite and digestive functions being unimpaired; but occasionally marasmus sets in, albumen appears in the urine, severe diarrh  a or pneumonia supervenes, and the case terminates fatally. In the great majority of cases, however, spontaneous recovery ensues in from six to twelve months after the occurrence of an indefinite number of relapses. The primary skin-trouble often reappears, and each recurrence is prone to be followed by a generalised exfoliative dermatitis of gradually increasing severity.

TYPE II. The relapsing, desquamative, scarlatiniform erythema of F  r  l represents the mildest form of primary exfoliative dermatitis. It is little known in this country. It is of more frequent occurrence in children and young adults than the other types. Its onset is well defined, with pyrexia (102  –104  ) and general malaise, sometimes even with sore-throat and a desquamating, scarlatinal-looking tongue. The eruption does not usually make its appearance for two or three days. It consists of an intense, more or less uniform redness, sometimes with small purpuric spots, but without any infiltration; its commonest situation is the legs, from which it spreads over the whole body. After its persistence for three or four days copious fine or coarse desquamation sets in, fever diminishes, and the redness begins to subside. At the end of a fortnight recovery is sometimes complete, but more generally repeated recrudescences prolong the duration of the disease over six weeks or two months. An accurate diagnosis in a first attack can only be a matter of surmise, but the subsequent course of the disease renders its nature indubitable. Relapses presenting the characters of the first attack invariably occur, and generally at regular seasonal intervals, most commonly in spring, when the return is usually attributable to a chill. With each relapse the severity of the disease tends to diminish, and finally perfect recovery generally takes place. It appears that sometimes the ingestion of certain drugs (especially mercurials) or the application of irritants (blisters, &c.) to the skin is responsible for the initial attack, which may be followed by relapses in the manner described. The disease is not infectious, and does not occur in epidemics; it is not accompanied by albuminuria, and loss of hair is very exceptional. A transverse groove on each nail is, however, generally left by each attack, while in the most severe cases the nails may be shed. This brings the disease into close relationship with the next type.

TYPE III. The primary universal exfoliative dermatitis of Erasmus Wilson is a less rare and more severe affection than the foregoing. Its objective characters may, in exceptional instances, be perfectly copied by cases of secondary exfoliative dermatitis, but the differences in clinical history and in their usual course justify their differentiation. As a rule, the subject attacked is a healthy adult male. The onset is acute, with rigors or chills, or may be insidious and accompanied merely

by 'malaise.' The temperature rises to 102° F. or higher; and until the eruption is on the wane it generally remains above the normal, with a marked evening rise. The eruption usually appears in the form of red erythematous patches, with fine desquamation, situated on the trunk, but it rapidly spreads, to become generalised over the whole body-surface. The skin is of an intense bright-red colour, but if exposed to cold often becomes of a dusky blue; in severe cases it is somewhat infiltrated, hard, and stretched. Soon the epidermis begins to exfoliate, and copious branny scales form and fall from the face, head, and neck; while large papery flakes are shed from the trunk, or remain attached by their centres, overlapping like slates at their margins. Two or three pints of such scales may be shed in the twenty-four hours. The skin of the palms and soles is usually detached *en masse*, and the redness there does not show itself until after the first exfoliation. The amount of itching varies within wide limits; generally it is severe, and sometimes it precedes the rash, drawing the patient's attention in the first place to it. Sometimes, however, there is no itching, and the subjective symptoms most commonly complained of are either tenderness or a sense of burning, while a feeling of cold is experienced by the patient as soon as he is exposed. Oozing from the flexures of the knees, elbows, axillæ and thighs sometimes occurs, and is often no doubt attributable, in part at least, to rubbing or scratching of the part. In a few very exceptional cases, bullæ have been observed in these situations, allying the disease with pemphigus foliaceus (p. 1175). The skin over the rest of the body remains intensely harsh, dry, and scaly, although from time to time copious sweating may occur. The scalp is extremely seborrhœic, while pustules, boils, and 'epidermic cones' surrounding lanugo-hairs are of frequent occurrence. The mucous membranes become involved; coryza, conjunctivitis, superficial glossitis, stomatitis, and pharyngitis may be observed; while the occasional occurrence of vomiting and diarrhœa probably indicates implication of the gastric and intestinal mucous membranes. The shedding of nails and loss of hair early in the disease are characteristic of this type; they may occur as early as in the fourth week. In a certain number of cases the general condition remains remarkably good, but in others the appetite is lost, the patient emaciates, and alarming prostration sets in. The appearance of albumen in the urine, or the development of pulmonary troubles or of diarrhœa, may usher in a lethal termination (generally in the third or fourth month); but undoubtedly in the majority of cases ultimate recovery occurs in from six to twelve months, after repeated disappointing recrudescences. As a rule, the redness first diminishes, then the scaling, and the two subside gradually together. Among complications and sequelæ Brocq enumerates carbuncles, abscesses, phlegmons, deafness, iritis, joint-troubles, cardiac complications, partial paralysis, paraplegia, and mental affections.

TYPE IV. *The primary, universal, chronic pityriasis rubra* of Hebra is a rarer and more grave disorder than the preceding. Its onset is always gradual, and unaccompanied by fever; it is evidenced by the appearance of dry, scaly, red patches, generally on the trunk, which gradually extend, to become universal after a period of several months or, it may be, years. The colour is usually dusky,

and the desquamation is always fine. There is little or no infiltration of the skin. Constant chilliness is complained of, but pruritus is seldom a troublesome symptom. Very gradually the skin becomes infiltrated, hard, brawny, and pigmented; then sclerosed, glossy, yellowish, and stretched over prominent bony points, or contracted round the orifices of the orbits and mouth (ectropion, eversion of lips). Slowly, also, but surely and without intermissions, the hair atrophies and falls out; and the nails become thin and crack, or much thickened and friable. Marasmus sets in after years, and the patient gradually sinks as the result of pulmonary tuberculosis, pneumonia, or diarrhœa. In the later stages ulceration and gangrene may hasten the fatal termination.

PATHOLOGY.—Of the intimate pathology of this group of diseases but little is known. Pye-Smith considers the dermatitis as primary; but there seem to be many valid reasons for considering the condition as essentially a vaso-motor and trophic neurosis, more probably of central than of peripheral origin. The co-existence of myelitis has been noted, and inflammatory changes in the peripheral nerves have been observed, but these are certainly not constant either in their occurrence or in their nature when present.

DIAGNOSIS.—This is usually easy; the history of the case, the universality of eruption, the intense redness and dryness of skin without marked infiltration, the absence of discharge, the characters of the desquamation and the moderate amount of itching, combined with the grave general condition, all serve to distinguish pityriasis rubra from extensive psoriasis, eczema, or lichen planus. Pemphigus foliaceus may be very hard to eliminate from the diagnosis, but generally its bullæ may be distinguished with their foul-smelling contents; it also occurs more frequently in women than in men. Epidemic exfoliative dermatitis (Savill) most closely simulates this disease; indeed, there seems to be no criterion for differentiating them beyond the history of the presence of an epidemic of the former, and the discovery and constant presence in the blood of persons attacked by it of a diplococcus of supposed specific nature.

PROGNOSIS.—The prognosis may be gathered from the study of any case in the light of the description of the various types given. Particular stress is to be laid upon the state of the appetite and digestion, and the presence or absence of albuminuria, pulmonary complications, and emaciation.

TREATMENT.—Treatment must be assiduous, and directed both to the local and general condition. The patient must be absolutely confined to bed, even in the mildest cases, and until recovery is complete, as the slightest chill is prone to cause relapse. He ought to lie between blankets, and on a spring mattress or water-bed. The diet must be nutritious but simple, including milk, in as large quantity as possible, eggs, milk-puddings, strong meat-soups or jellies. Alcohol ought not to be prescribed, unless the prostrated condition of the patient demands it; and then sound wine is preferable to spirits, as causing less thirst and gastric disturbance. Cod-liver oil is sometimes of use when emaciation is marked. Iron appears sometimes to be detrimental, but quinine in an effervescing citrate-of-potassium mixture is certainly sometimes useful and grateful to the patient. Diuretics, such as acetate of potassium with digitalis, are

frequently employed and probably beneficial. The promotion of free diaphoresis by jaborandi or the subcutaneous injection of nitrate of pilocarpine has been advocated by Stephen Mackenzie and others. Linseed oil in large quantities, both externally and internally, has been lauded by Sherwell. The bowels must be carefully regulated, preferably with mineral waters and salines, the latter often profitably combined with the liquid extract of cascara sagrada. There is a general consensus of opinion that arsenic is worse than useless in the earlier stages, while few writers accord it anything but faint praise even in the later. The writer has been disappointed with the effects of antimony. He has also noticed aggravation of the eruption after the administration of opium, chloral hydrate, belladonna, and Cannabis Indica, with a view to obtaining sleep.

Oily external applications are certainly the most beneficial. The calamine-liniment recommended by Radcliffe Crocker is an admirable preparation. It is composed thus: Calamine 40 grains; oxide of zinc 2 drachms; olive oil and distilled water, each 1 fluid ounce. The patient may be swathed in rags soaked in this liniment, slightly warmed if necessary. The pharmacopœial linimentum calcis is also useful, as is a lotion consisting of an ounce of glycerole of lead and of glycerine in a pint of water, similarly employed. Pure vaseline is occasionally a valuable substitute.

Prolonged warm baths may be of service in diminishing itching, but are apt to be followed by increase of cutaneous hyperæmia. This risk is materially diminished by the addition of bran (6 lbs.), linseed (1 lb.), gelatine (3 lbs.), or potato starch (1 lb.) to the thirty-gallon bath. The further addition of two or three ounces of borax or bicarbonate of sodium is often advantageous.

Pityriasis Rubra Pilaris (Devergie-Richaud).

SYNON.: *Lichen ruber acuminatus* (Hebra).—

This disease, the ætiology of which is not known, is insidious and non-febrile in its onset, young persons being frequently its subjects. The writer has seen one case in a child two years old. Desquamative, psoriasiform patches on the palms and soles; a seborrhœic, eczematoid condition of the scalp, or a fine branny scalliness of the face are the commonest initial symptoms. Sooner or later the characteristic lesions appear upon the limbs or body, especially where hair is abundant, in the form of small brownish-red, firm, dry, conical papules, seldom larger than a millet-seed, and surrounding atrophied hairs. These 'epidermic cones' give the skin a harsh and grater-like feeling to the touch; they send little plug-like processes into the follicles, from which they can be dislodged by rubbing, leaving fine cribriform pits. As the disease progresses these lesions become confluent, when their characters are lost, and yellowish, infiltrated, desquamating patches are formed which may closely resemble psoriasis, especially about the elbows and knees. A few typical primary lesions are usually present for some time about the periphery of these patches. The surrounding and intervening skin subsequently becomes red and infiltrated, with desquamation either of fine, branny, or coarse mortar-like character, and the condition may become practically universal; the palms and soles, where there are no hair-follicles, are usually conspicuously involved, being hyperæmic and scaly. The primary lesions generally retain their characters on the backs of the first and

second phalanges of the fingers and toes, where they are almost pathognomonic of the disease. Severe seborrhœa capitis is always present, and the hair may fall in quantity; on the other hand, hypertrichosis of the affected parts has been noted in some cases. The nails are usually soft and transversely striated, or may become enormously hypertrophied and claw-like. The face assumes a peculiar powdered appearance, owing to the dry, white scales lying on the reddened skin, and sometimes ectropion results from contraction. Itching is usually slight, if present at all.

PATHOLOGICAL ANATOMY.—The essential lesion is a hyperkeratosis of the epithelium lining the hair-follicle, to the bottom of which it penetrates. This hyperkeratosis extends to the epithelium of the general surface of the skin and, to a slight extent, affects the sweat-ducts. The inflammatory phenomena in the cutis are secondary.

DIAGNOSIS.—This disease must be distinguished from follicular ichthyosis (keratosis), lichen pilaris, psoriasis, and pityriasis rubra, to all of which reference may be made.

PROGNOSIS.—Recovery always takes place, but the duration of the disease is quite indefinite, being frequently marked by remissions and exacerbations without ascertainable cause.

TREATMENT.—The production of diaphoresis by active exercise, Turkish baths, and pilocarpine is probably beneficial. Arsenic is useless, if not actually harmful. The local treatment may be conducted on the lines laid down in Pityriasis rubra and Ichthyosis. J. J. PRINGLE.

PITYRIASIS VERSICOLOR (πίτυρον, bran). See TINEA VERSICOLOR.

PLACENTA, Diseases of.—Comparatively little is known of placental diseases. This is explained by the fact that the normal structure of the organ at different stages of pregnancy has only in recent years been clearly defined; pathological work had been founded upon an inadequate anatomical basis, and many of the earlier investigations of supposed morbid conditions have been invalidated by later knowledge of the normal structure. In this article, accordingly, only such matters will be referred to as are now fully established by recent research.

Changes due to Ripening.—It has been shown by Whitridge, Williams, the present writer, and others, that during the last two or three months of pregnancy certain changes occur in the placental tissues which are preparatory to the process of shedding during labour. Briefly stated, these changes consist in obliterating endarteritis of the foetal arteries leading to atrophy of the chorionic epithelium, to the formation of numerous solid patches in the spongy placental tissue, termed *infarcts*, and to extensive deposition of fibrin from the maternal blood upon the villi in the affected areas. Numerous groups of villi are thus rendered functionless. These changes are in reality senile, and not due to disease at all, but they have frequently been erroneously attributed to inflammation, hæmorrhage, or syphilis.

Changes in Retained Placenta.—When the foetus dies and the ovum is not discharged from the uterus, certain well-defined changes occur in the placenta as a result of the suspension of the circulation through it. These changes consist in extensive formation of blood-clot, in atrophy of villi, and in the

deposition of large quantities of fatty and calcareous material in the altered structures (fatty and calcareous degenerations). These changes, which are in reality *post mortem* (following the death of the foetus), have been frequently cited as the morbid conditions to which the death of the foetus was due, and in this way much confusion has been introduced into the pathology of the placenta.

1. Inflammation (Placenteritis).—So far as is known placenteritis does not occur except as the result of septic or gonorrhoeal infection of the uterine cavity. Retained placental fragments are especially liable to undergo putrefaction, and the whole ovum may become involved in uterine gonorrhoea or sepsis. A dead ovum which has been retained *in utero* for a prolonged period occasionally undergoes putrefaction even if no operative interference of any kind has been practised, infection, in such cases, probably occurring from the bowel. It is possible that the condition known as Morbid Adhesion of the placenta is the result of an inflammatory affection of the decidua serotina, but in any case the foetal portion of the organ is not involved in the process.

2. Hæmorrhage.—The conditions known to obstetricians as Placenta Prævia, and Accidental Hæmorrhage, are instances of hæmorrhage from separation of the placenta from the uterine wall, and in both instances bleeding frequently occurs during the last two months of pregnancy before the onset of labour. In both the placenta is usually healthy, but in the latter morbid conditions are not infrequently present which may cause the premature detachment of the organ. The subject will, however, be found more fully discussed in another place (see PREGNANCY, Diseases of). We are not concerned here with hæmorrhage into the chorion before the formation of the placenta, i.e. during the first three months of pregnancy. This subject is treated under 'Molar Pregnancy' (p. 1016).

Hæmorrhage into the substance of the placenta occurs in two widely different forms: (a) Small interstitial hæmorrhages; (b) Large effusions often termed 'placental apoplexy.'

(a) *Interstitial hæmorrhages* are not uncommon; they occur in the form of black circumscribed areas which stand out in marked contrast to the purplish colour and reticulated structure of the healthy placental tissue. There may be many such small areas scattered through the organ, or an entire cotyledon may be thus affected while the remainder of the placenta is healthy. Under the microscope the hæmorrhagic areas are seen to consist mainly of blood-clot, with a few widely separated villi here and there, which are usually broken or distorted in appearance but otherwise normal. These 'hæmorrhages' appear to be the result of a relatively excessive afflux of blood to the maternal spaces of the affected part, or some hindrance to its return. Speaking strictly, the condition is not hæmorrhage, because the blood is still contained in the inter-villous spaces, and has not escaped from its normal channels. But it differs from mere congestion or engorgement of vessels, inasmuch as the surrounding villi are broken up and their relations altered by the process. It is, therefore, better to regard the process as hæmorrhage. Interstitial hæmorrhages do not appear to affect the functional capacity of the placenta to an extent sufficient to react unfavourably upon it. It is probable that they are often produced during labour by the in-

fluence of the uterine contractions upon the maternal placental circulation.

(b) *Large effusions of blood* are much rarer than the interstitial hæmorrhages just described; they are more rapidly produced, and therefore break up the placental tissues to a greater extent than the interstitial ones. In consequence irregular cavities of considerable size containing blood-clot are formed in the substance of the placenta, limited, in recent cases, by compressed and broken villi, and in older cases by layers of fibrin forming a false capsule. In some of these cases the hæmorrhage is fatal from rupture of a branch of the umbilical vessels within the placental tissue; oftener the blood is maternal, and then the cavity generally communicates with the circular sinus. The effused blood first accumulates in the placenta, and may then burst through the serotina, causing some separation of the placenta from the uterine wall. These hæmorrhages invariably cause the death of the foetus, or lead to almost immediate abortion. They occur in association with maternal albuminuria or chronic nephritis, or with valvular lesions of the heart (maternal); if associated with albuminuria, pathological infarction is often found in the areas unaffected by the hæmorrhage. If abortion does not immediately follow, the changes which usually occur in effused blood are found, viz. clotting with partial organisation or degeneration.

The clinical diagnosis of placental hæmorrhage at the time of its occurrence is not practicable; the amount of blood effused is not large enough to cause constitutional symptoms.

3. Œdema.—Œdema of the placenta is usually associated with œdema of the foetus, and the causes of the two conditions appear to be the same. Instances have been recorded where obstruction to the foetal circulation from intra-uterine closure of the foramen ovale, or thrombosis of the umbilical and hypogastric vessels has been the cause of the œdema; the placenta of acardiac and other monsters is also often œdematous. Anasarca of the mother as from renal or cardiac disease has often been noted, and syphilis is also said to cause it. Virchow and Franck have observed that in general dropsy of the foetus of bovine animals the thoracic duct and mesenteric lymphatics were absent, but this point does not appear to have been ever investigated in the human foetus.

An œdematous placenta is larger, heavier, and paler than normal, and undergoes a great diminution in weight if incised and the fluid allowed to drain away from it. The normal weight of the placenta is about 16 ounces; an œdematous placenta frequently weighs twice that amount; the heaviest on record weighed 56 ounces. On microscopical examination the stroma of the villi and the larger chorionic branches is seen to be the seat of the œdema, and in two specimens which the writer has examined fatty degeneration was also present. When the placenta is œdematous the foetus born with it is usually dead, and often macerated, showing that death occurred some time before labour set in, but, as has been already stated, other morbid conditions of the foetus or the mother are frequently associated with it.

4. Pathological Infarction.—It has been already stated that during the last two months of intra-uterine life certain changes referable to senility occur in the foetal placenta resulting in the formation of small solid bodies termed 'infarcts.'

in the spongy placental substance. In healthy conditions these are neither large enough nor numerous enough to interfere with the functional capacity of the placenta or the development of the foetus. Within the last decade it has been shown that changes similar in their nature, but occurring much earlier in gestation, and affecting a much larger proportion of the placental tissues, are found in connection with a well-defined maternal disorder—albuminuria of pregnancy. This disorder is known to depend either upon chronic nephritis pre-existing pregnancy, or upon a transient form of renal disease which frequently develops during pregnancy and disappears rapidly after labour. A heavy foetal mortality, estimated at about 54 per cent., has long been known to accompany this condition, and there is good reason to believe that the changes which occur in the placenta are the cause of the death of the foetus. In a marked example a considerable proportion—one-third to one-half—of the placental substance is converted into a firm, yellowish, bloodless tissue, which is seen under the microscope to consist of large deposits of fibrin surrounding atrophied chorionic villi, both elements usually showing marked fatty degeneration. Advanced obliterative endarteritis is found in the foetal vessels, where these can be distinguished. Hæmorrhages are frequently found in non-infarcted portions of the placenta. Cases in which labour occurs at the sixth or seventh month frequently show an extreme degree of these changes, and, generally speaking, cases which go nearer to term show less marked changes than those in which labour comes on earlier, although it is rare, in any case, for pregnancy to advance beyond the thirty-sixth week in this condition. In addition to these changes in the placenta, the foetus is smaller and of less weight than the healthy foetus of the corresponding period; it is, in fact, under-developed and possesses little vitality. The foetus suffers, apparently, in direct proportion to the extent of the placental changes, and there is little doubt that these changes exert an unfavourable influence upon its development. Labour is frequently delayed for some time after the death of the foetus, which is then born in a macerated state.

The manner in which the placental changes affect the foetus is sufficiently clear. The infarcted portions of the placenta are functionless because both the foetal and maternal circulation through them have ceased; the villi are atrophied and devascularised, while the maternal inter-villous spaces are obliterated. If a large portion of the placenta is thus affected, the remainder is inadequate to the task of depurating and enriching the foetal blood; the nutrition and development of the foetus therefore suffer. If hæmorrhage should occur into the non-infarcted portions, the foetus will probably perish suddenly; some separation of the placenta from the uterine wall may occur at the same time, leading to accidental hæmorrhage, or there may be no sign until labour sets in. The ætiology of the placental changes is not so clear. Women suffering from albuminuria during pregnancy are generally very anæmic, and there is extensive anasarca: there is some evidence of the existence of a toxæmia in the albuminuria of pregnancy. Impurities may therefore pass through the villi into the foetal circulation, and, by contact with the walls of the foetal vessels, induce the process of obliterative endarteritis, which is probably the initial change.

5. Degenerations.—The tissues which compose the placenta are embryonic in type and prone to degeneration of various kinds.

a. Vesicular Degeneration (Hydatidiform Mole) is a form of myxomatous degeneration of the chorionic stroma which usually occurs at an early period before the differentiation of the placenta takes place; it therefore affects the chorion rather than the placenta, and will be found fully described in another place (p. 1017). In rarer instances it occurs later in gestation and then affects the placental chorion. The disease has then the same general characters as in the hydatidiform mole, but the whole placenta is seldom or never attacked by it; usually one or more cotyledons suffer while the remainder of the organ escapes. The life of the foetus is apparently always destroyed, for no instance is on record where the placenta of a living foetus has been found to be affected by this disease.

b. Fatty and Calcareous Degenerations.—A certain amount of fat is present in the normal human placenta, being located in the superficial layers of the decidua and in the plasmodial layer of the chorionic epithelium (syncytium); it occurs in minute non-confluent droplets, and its total amount is very small. Fatty degeneration is most commonly found as a sequela of pathological infarction in albuminuria, and is then to be referred to malnutrition from extensive obliteration of the foetal vessels. Along with other conditions such as cedema, and in placenta retained *in utero* after the death of the foetus, it is also not uncommon. A deposit of lime-salts—calcareous degeneration—not infrequently occurs in parts which have undergone fatty degeneration. In a fully ripe placenta it is usual to find small thin calcareous plates upon the uterine surface; they are located in the decidua serotina and do not as a rule involve the chorionic villi. Cases have been recorded where the uterine surface has been thus almost covered with a plate of calcareous material, the deposit occurring chiefly in the decidua serotina.

c. Cystic Degeneration.—Cysts occur but rarely in the placenta. They are, however, occasionally observed upon the foetal surface of otherwise healthy placenta in the form of small, multiple collections of clear, yellowish fluid. The amnion can be readily peeled off them, as they are situated in the chorionic membrane; more rarely still, similar cysts are found in the amniotic membrane itself. They are produced by myxomatous degeneration of the connective tissue of the membrane in which they lie, and possess no epithelial lining, their walls being formed of degenerating and compressed connective tissue. The connective tissue of the foetal membranes is embryonic in type and very prone to this form of degeneration. Cysts on the foetal surface of the placenta never exceed the size of a pigeon's egg, and do not interfere in any way with the functional activity of the organ. Infarcts, when incised, are often found to contain cystic cavities with ragged, irregular walls in their interior. These cavities are formed by necrosis and they contain a thick pulpy fluid consisting of *débris*.

Myxoma fibrosum.—This is a peculiar form of myxomatous degeneration with hypertrophy of the chorionic villi. It was first described as a new-growth, but is more accurately classed as a form of degeneration. It is a very rare disease. Usually only a portion of the placenta—perhaps one cotyledon—is affected, and this portion is greatly

increased in size so as to form a protuberance upon the uterine surface; hence its classification as a form of new-growth. On microscopical examination the protuberance is found to consist of enormously enlarged villi, the enlargement being due to myxomatous degeneration of the stroma accompanied by the formation of a certain amount of connective tissue of adult type. The chorionic epithelium is not much altered. The change is thus closely allied to that found in vesicular degeneration of the placenta, the chief difference being the formation of connective tissue in the latter, which greatly alters the gross characters of the affected part.

6. Tubercular disease.—In cases of chronic miliary tuberculosis, and in cases of advanced chronic phthisis, tubercle has been occasionally found in the placenta. The deposit occurs in the substance of the organ and is recognised by its well-known macroscopic and microscopic characters. Very few cases have been recorded, but in a considerable proportion no tubercular changes could be found in the body of the fetus, although the placenta was extensively involved.

7. Decidual Endometritis.—This condition is not strictly a disease of the placenta, for it affects the decidua in all parts, and usually commences at a period preceding the formation of the placenta. It occurs in two distinct forms, the *glandular* and the *interstitial* form. The former corresponds to the common or glandular form of endometritis of the non-gravid uterus; the decidua membrane is thickened and frequently shows small polypoid swellings upon its surface, but no actual inflammatory changes at all; the condition is rather that of glandular proliferation than of inflammation of the tissues. The interstitial variety is rarer; this is a true inflammatory condition characterised by round-cell infiltration of the whole membrane with intense congestion and many interstitial hæmorrhages. It has been shown that this form may be due to the gonococcus, which organism has been demonstrated in the affected membrane. Acute hæmorrhagic endometritis in pregnancy is also said to occur from cholera and the acute exanthemata.

The symptoms associated with decidual endometritis are pain and hæmorrhage during the first three months of pregnancy, and a marked tendency to abortion. If the ovum survives that period, atrophy of the decidua vera and reflexa will occur, and the danger is lessened. Diagnosis can only be established by microscopical examination of the discharged membrane. It is possible that morbid adhesion of the placenta in labour is a sequela of this condition. T. W. EDEN.

PLAGUE (πληγή; *plaga*, a stroke).—**SYNON.** : The Pest; Inguinal, Bubonic, Glandular, Oriental, Indian, Pali, and Levantine Plague; Oriental Typhus; Septic Pestilence; Fr. *La Peste*; Ger. *Die Pest*.

DEFINITION.—An acute infectious disease caused by a specific micro-organism which enters the body by the lymphatic or respiratory systems, the disease taking on the bubonic or pneumonic type according to the mode of infection. The bubonic form is the most common, is distinguished by fever, giddiness, debility, inflammatory swelling of the glands, external or internal, with serous or hæmorrhagic effusion from them into the surrounding tissues, more especially in the region of the groin, arm-pit, or neck, and occasionally accompanied by boils or

carbuncles, petechiæ or pustules. The pneumonic form is characterised usually by no glandular swellings but by acute fever, intense prostration, and slight cough with sputum tinged with blood and containing plague-bacilli. The disease affects the lower animals, especially rodents, and becomes epidemic among rats and mice.

ÆTIOLOGY.—The causal agent of plague is a bacillus discovered by Kitasato and later independently by Yersin. It is a short thick bacillus with rounded ends, staining with all the ordinary dyes, and taking the stain more easily at the poles than in the centre. In one form it is like a coccobacillus, in another like a diplo-bacterium. In a plague-patient it is found in the primary bubo and peri-glandular effusion before suppuration commences, in the blood in the more severe forms and later stages of the disease, and in the sputum in the pneumonic form of plague. In the corpse it is found in the organs and fluids of the body. It grows readily on the ordinary media employed for microbes. On agar the colonies show themselves as small opalescent spots with iridescent borders on reflected light. On gelatine they have the appearance of spots of white wax; they do not liquefy the gelatine. In broth there is after twenty-four hours a deposit at the bottom of the liquid which generally remains clear; after two days a film forms on the surface. In cultures the microbe may appear singly or in chains. Involution-forms of the bacillus are often to be found in the contents of the bubo and in the cultures from them, more especially in old and dry agar-cultures. Alongside of the coccobacilli and diplo-bacteria there are irregular elements resembling yeasts or algae in the form of swellings, gours, and bladders. These polymorphic forms are less easily stained than the typical coccobacilli and may be mistaken for impurities. On cultivating the microbe in broth, to which drops of clarified butter or cocoa-nut oil have been added, a very characteristic growth is obtained. This is called 'Haffkine's stalactite test.' From the drops of oil suspended on the surface of the nutrient medium the bacilli grow down into the depths of the liquid in the form of long threads producing the appearance of stalactites. When disturbed the threads fall in snow-like flakes to the bottom. This stalactite-formation is, under these conditions, peculiar to the growth of the plague-microbe, no other microbe having hitherto been found to possess the same property.

Inoculation of the bacillus into guinea-pigs, rats, and mice produces in them a septicæmia which proves fatal in the course of three to five days. At the site of inoculation there is a sanguineous effusion and the nearest glands are swollen and infiltrated; there is also general congestion of the organs, and hæmorrhages are common in the lungs, heart, liver, and serous cavities. The disease produced is similar to plague, in men the principal lesions being buboes, extravasations, and congestions in the internal organs. In rats and mice the glands and organs contain the bacilli in extraordinary numbers.

An accident in Vienna in October 1898 placed beyond doubt that the bacillus is the causal agent of the disease. Some cultures of the bacillus were brought to Vienna from Bombay by the Austrian Commission. With these cultures experiments were made on animals. Nearly a year after the return of the Commission, Franz Barisch, the

assistant of the Pathological Institution in Vienna, in charge of the experimental animals, fell ill with pneumonic plague. Dr. Mueller and two nurses became infected by Barisch before the disease was stamped out.

The Plague-Bacillus in the Lower Animals.—Usually an epizootic among rats or mice has been observed to precede or accompany an epidemic of plague in man. The rats leave their hiding places and come out into the open in great numbers. They appear very ill, are in a dazed or stupefied condition, their eyes are watery and bleary, their coats are partially deprived of hair, and they hobble about with difficulty, staggering and falling over one another. They lose their timidity for man in their evident desire for fresh air, and they fail in energy even to attempt to escape when approached. The sick and the dead are often heaped together. Examined after death the glands in the groin, axilla, or neck are found to be enlarged, congested, and agglutinated, the internal organs congested and the spleen and liver enlarged and full of bacilli. It is now established that these bacilli are identical with the plague-bacilli in man, and that the epizootic in rats or mice and the epidemic in man are identical in their causation. Though rats and mice are most liable to contract plague under natural conditions, other animals are susceptible, such as monkeys, bandicoots, squirrels, pigs, sheep, cats, dogs, and marmots. In the Transbaikal province of Eastern Siberia and in Eastern Mongolia, a species of marmot called the Tarbagan (*Arctomys bobac*) suffers from a disease which is believed to be plague and which is transmitted from the marmot to human beings.

MODE OF INFECTION AND DISSEMINATION.—Plague can be caused experimentally in a rat or a monkey by the single prick of an infected needle without the production of a visible wound. For this purpose it is sufficient to smear the bacilli over the shaved surface of a guinea-pig or other small animal; to rub them on an intact skin; to squirt them on to the conjunctiva or the Schneiderian membrane, or to feed the animals with cultures. It is believed that by similar means the plague-bacilli gain a lodgment in the lymphatic system of the human body, viz. by the skin, mucous membrane of the nose and mouth, especially of the tonsils, the conjunctiva, respiratory system, and occasionally by the alimentary canal. Two explanations are advanced as to the method of infection from rats to men. One is that the plague-bacilli on the rat infect men through wounds or scratches on the hand or feet. The other, which is propounded by Simonds, is that the fleas infesting rats, and which have been found to contain plague-bacilli, convey the infection to man as well as to healthy rats. The rats are infected from man by means of infected articles belonging to him. In 1896 a man from Bombay, whose wife had died of plague, brought her clothes home to his village, which had hitherto been quite free of plague. In a short time the rats in this man's house began to sicken and die, after which the inmates were attacked with plague and died, the man himself not being attacked till five of his relatives were affected.

CLINICAL FEATURES.—The clinical features depend more or less on the type of plague with which the patient is attacked. The principal types are the bubonic, septic, pneumonic, and ambulant. It not infrequently happens, however, that as the dis-

ease progresses, either the type becomes mixed, as when the pneumonic supervenes in a bubonic case, or there is a transition from one type to another, as from simple bubonic to septicæmic plague.

Premunitory symptoms are frequently absent, or, at all events, little marked. When present they consist of a slight indisposition for one or two days, with loss of appetite, heaviness in the head, headache, nausea and giddiness, weakness and sometimes pains in the limbs. There is nothing characteristic. The usual course is for the illness to set in suddenly, with rigors, high fever, severe headache, great giddiness, and nausea.

There are certain *general symptoms* which are common to all severe forms of plague. These are the peculiar expression of the face, the halting speech, the appearance of the tongue, and the staggering gait. The countenance in the early stages depicts anxiety and distress, in the later stages resignation and apathy, the vacant expression often marking the approaching dissolution. When delirium is present the expression may be one of terror. The eyes are red and congested, the conjunctiva being injected, but there is no photophobia. The patient has the appearance of being under an hypnotic, yet he is awake with eyes wide open. The speech is stuttering, thick, lisping, more or less staccato in character, and indistinct, often like that of a drunken man. When spoken to, the patient often begins a sentence and forgets to finish it. The tongue is early coated with a whitish fur, later it is dry, covered with a yellowish or whitish brown fur, except at the top and edges, which are irritable and red. The gait is staggering, owing to giddiness; there is a great tendency for the patient to fall. In many plague patients there is a desire to wander and there is a difficulty in keeping them in bed. This desire to wander is attended with great danger to the patient owing to the weak condition of the heart, causing a faint which may never be recovered from.

The Bubonic Form.—The ordinary bubonic plague is unlikely to be confused with other diseases. There may or may not be any premonitory symptoms, such as malaise and rigors. The disease usually begins with sudden fever, rising to 103° F. to 104° F., or even to 105° F., with nausea, vomiting, and severe and intense headache, mostly frontal or occipital in its seat. The eyes are suffused and congested, there is great giddiness and the tongue is furred, except at the tip and at the edges. None of these symptoms distinguish it specially from the onset of other acute infections; but, contemporaneously with the fever, or soon after its appearance, intense pain is felt in the groin, the armpit, or the neck, and at the seat of the pain one or more of the glands will be noticed to be swollen and to be particularly painful on pressure. In the course of twelve hours, or even in a shorter time, the swelling rapidly increases in size. This increase is caused by a periglandular effusion, which may be very profuse or only moderate in extent; and the bubo which is thus formed is somewhat doughy to the touch on the surface, and of a hard consistence in the deeper tissue. This bubo, with the other signs, is pathognomonic of plague. It is filled with plague-bacilli. The bubo may appear in the groin, armpit, or neck, and occasionally in the supra-trochlear or popliteal space. The most common site is the groin, and the next is the armpit; but more than one region may be affected, and often groups

of neighbouring glands on the same course of lymphatics become infected. The bubo varies in size, and consists of one or more inflamed lymphatic glands, from which exudes a sero-sanguinolent effusion which mats together the neighbouring glands into a hard mass of glandular tissue and extravasated blood, and infiltrates the tissues around, rendering them firm and oedematous. The oedema may be scanty or profuse. In cases which prove fatal early, the glands may remain hard and painful. In the groin the bubo may reach the size of a man's fist, and may extend into the iliac region, affecting the chain of glands in the abdominal cavity and forming a hard tumour, to be felt through the abdominal wall. In the axilla the bubo often occludes the axillary space, and the infiltration may become so extensive and organised as to form a hard mass which may interfere with the respiratory movements, or become a dangerous slough. In the cervical region the oedema may be so great as to be a serious danger to the patient, and by pressure to produce stridulous respiration, the tonsils and throat generally being inflamed. The position of the patient in bed is always one which tends to relieve as much as possible any tension on the bubo. There is no relation between the volume or size of the bubo and the amount of pain it causes. Consciousness is ordinarily retained, but even apparently with the most perfect consciousness the intellect is slow in answering questions, and the words or sentences are articulated in a hesitating manner, each syllable being pronounced slowly; or the speech is staccato in character, and uttered in an irritable and hurried tone. The temperature is not characteristic. It may reach its maximum in a day or two, or not until the fourth day. It is of a remittent nature, and in favourable cases begins to decline on the sixth and seventh day, and reaches the normal on the tenth day. The symptoms usually attain their height on the fourth day. Restlessness, with a desire to get out of bed and wander, is often a prominent symptom. Dyspnoea and delirium of a quiet or a noisy nature set in, followed in unfavourable cases by coma and gradual or sudden failure of the heart's action. The pulse, which is soft and easily compressible at the outset, becomes intermittent and dicrotic and often difficult to count, and the extremities become cold and clammy. Recovery, when it occurs, usually sets in about the sixth or seventh day, but no prognosis is safe in the early days of the illness. In addition to buboes there may be plague-carbuncles, which sometimes appear over the primary bubo, and secondarily to it or in other parts of the body, either before or after the appearance of the bubo.

The Septic Form.—The septic form of plague is a virulent type in which the lymphatic glands show no special enlargement during life, and consequently the bubo is absent or not readily recognised, but after death the glands are found to be generally affected, being somewhat enlarged and much congested. In this form of plague, the bacilli invade the blood in large numbers at an early stage and are easily detected during the life of the patient. The chief characteristic is its rapidity. The patient is profoundly affected by the amount and strength of the poison received. Usually ushered in with high fever, there is at times no power in the patient for reaction, and the temperature does not reach 100°. The countenance is pale and the expression apathetic. Extreme nervous prostration, muscular

weakness, delirium, picking of the bed-clothes, stupor and coma follow quickly on one another, and the patient dies on the first, second, or third day. In these cases there may be bleeding from the nose, kidneys, and bowels.

The Pneumonic Form.—This variety is very infective, and owes its infectivity to the fact that the sputum frequently contains almost a pure culture of plague-bacilli, which get on to handkerchiefs, clothing, bedding, and other articles of furniture, as well as on to the floor of the patient's room (Childe). The clinical symptoms are not typical of ordinary plague, and the disease is likely to be mistaken for bronchitis, broncho-pneumonia, or pneumonia. Pain, tenderness, and enlargement of the lymphatic glands in the inguinal, femoral, axillary and cervical regions—symptoms which are the most prominent external signs of bubonic plague—are absent unless the pneumonia is a complication of bubonic plague; and beyond cough and fever and a prostration which is exceptionally severe and far exceeding that likely to result from the small amount of lung-mischief discernible, there are few signs to raise suspicion that the disease is plague. The illness commences with a rigor and symptoms of general malaise, intense headache, nausea, vomiting, and pains in the limbs and body, followed by fever varying in range from 102° to 105° F. Cough more or less pronounced with dyspnoea sets in, and a quantity of watery sputum tinged with blood and becoming profuse as the disease advances is coughed up, as a rule, without effort. The sputum has not the glairy, viscid, rusty character of acute pneumonia, though on the clothes it may be readily mistaken for this. The physical signs are moist sounds at the base of the lungs and over the pneumonic patches, the pulse and respiration are rapid, but there is not the same disproportion in their ratio as is observed in acute pneumonia. The symptoms become rapidly worse, the patient becomes delirious, and usually dies on the fourth or fifth day or earlier. This type is the most infectious, and the most fatal. It corresponds with the black death of 1348. The sputum teems with plague-bacilli.

Ambulant or Mild Form.—The ambulant or mild variety of plague is even more likely to escape attention than the pneumonic, because of the slight constitutional disturbance which it may produce, and because it is often taken for some other disease. It is not discernibly infectious, the cases appearing to crop up unconnected with one another. And it is generally mistaken in the early stages of an epidemic for mumps, syphilis, the result of a strain, serofulous glandular affections, and malarial disease. The clinical symptoms are ill defined or well-defined fever, pain, tenderness and enlargement of the lymphatic glands in the groin, axilla, or neck, weakness, a tongue which is coated with a creamy white fur in the centre and is angry and red at the tip and edges. The eyes may be slightly congested, and the speech a little thick. This is the acute form which may only last a week, the bubo resolving rapidly or quickly suppurating. In the more chronic form, which may last two or three months, the bubo or buboes are indolent, and they undergo a slow process of suppurating and sloughing, constituting at times a serious drain on the general health of the patient producing anæmia and debility. These mild or benign forms of plague, often called 'pestis minor,' have been observed in nearly all plague-epidemics. The most recent example of this form

of plague unmixed with other varieties was the glandular sickness, as it was called, in Astrakhan in 1877. In this city an outbreak which affected more than 200 persons occurred without a single death and without being followed by the virulent form. Those affected suffered from fever more or less acute, with swellings and inflammation of the lymphatic glands, which in most cases ended in abscesses. Beyond the inconvenience and discomfort caused by the buboes, sometimes in the neck, sometimes in the armpit, and at other times in the groin, the general symptoms were not such as to prevent the patient from pursuing his ordinary avocations. About the same time there prevailed at Resht in Asia Minor, with which Astrakhan has more or less communication, the same type of glandular sickness along with a severe type of plague. In the next year, in 1878, the glandular sickness of Astrakhan appeared at Vetlianka, a village on the banks of the Volga and some distance from Astrakhan; but in a short time it was succeeded by a most virulent type of plague which assumed the pneumonic form and was of an extremely infectious and fatal character. The mortality at the height of the epidemic, which was limited in its extent, was 100 per cent. Mild cases intermixed with severe have been noticed in many epidemics. Mild cases of plague were observed in Calcutta, Bombay, Alexandria, and Oporto some time before the fatal cases attracted attention. In Calcutta, examination of the blood from the affected gland showed in some cases the characteristic bacillus, but in others none could be detected.

MORBID ANATOMY.—Decomposition of the corpses is not accelerated in plague, unless in the mixed forms, when streptococci are present. On the skin there are often small hæmorrhages, chiefly in the vicinity of the bubo, and on the head, arms, neck and shoulder; these hæmorrhages contain plague-bacilli. Hæmorrhages are often found in the muscles, chiefly in those of the abdomen and of the temporal bones, as well as in the muscles near the primary bubo; they contain polynuclear leucocytes and plague-bacilli. The characteristic appearance in a necropsy of plague is that of engorgement and hæmorrhage, nearly every organ of the body participating more or less. There is also parenchymatous degeneration and change in the heart, liver, spleen, and kidneys. Pathological appearances special to plague occur in the lymphatic glands, lungs, liver, and spleen. There is no other acute infectious disease which shows a similar multiple inflammation of the lymphatic glands. The enlargement of the lymphatic glands may be classed as hæmorrhage. The appearance of the glands depends on the type of the disease and the time at which death takes place. The primary bubo consists of a number of congested glands embedded in a mass of extravasated blood with extensive exudation into the adjoining areolar tissue, the larger blood-vessels being often involved. This infiltration contains polynuclear leucocytes and plague-bacilli. The glands in the bubo are swollen, varying in size from a bean to a walnut. They present a blackish-red appearance, and where cut into are found to be much congested and of a dark purplish colour. In cases in which death takes place later, the swollen and infiltrated glands show signs of commencing necrosis, while in cases in which death does not occur till the eighth or ninth day the necrosis has advanced, the paren-

chyma of the gland contains a yellow or reddish-yellow pus enclosed by the capsule, and the severe changes in the vicinity of the lymphatic gland have usually improved. The inner walls of the adjoining veins near a primary bubo are suffused in large patches, or are permeated with smaller hæmorrhagic points. The vein itself is surrounded by a copious inflammatory exudation, giving the tissue around a yellow gelatinous appearance. From the primary bubo a chain of swollen glands may be seen extending to other parts of the body.

In the septicæmic and pneumonic forms, in which the primary bubo is absent, nearly all the lymphatic glands are slightly enlarged and pink or dark red in colour; some may be engorged. In the pneumonic form there are, in addition to the general engorgement of the lungs, common to all forms of plague, several pneumonic patches, usually scattered but occasionally connected so as to form large areas together with extravasations on the pleura. The patches have the general appearance of red hepatization with an enveloping zone of intense congestion. The spleen is usually enlarged, and in the septicæmic and pneumonic forms of plague contains hæmorrhagic infarcts. Plague-bacilli are to be found in the different varieties of plague, in the lymphatic glands and the serous or sanguinolent exudation around them, in the blood, spleen, lungs, bile, urine, peritoneal fluid, and fluid of the brain. In the pneumonic cases they may be found only in the lungs and the bronchial glands.

DIAGNOSIS.—The difficulty of diagnosis of plague arises from the several types and forms which the disease assumes. In the epidemic in Bombay in 1896, some of the earlier cases with swollen glands and throat-symptoms were mistaken for diphtheria. In Jeddah, where pulmonary symptoms predominated, the earlier cases were taken for influenza; in Asencion for yellow fever and gastro-enteritis; and in other places the ambulant or mild form has been mistaken for non-venereal bubo, syphilis, malaria, parotitis, and even the effects of strain or accident. At the commencement of an epidemic the clinical symptoms are often obscure, and bacteriology alone can elucidate the question. When fever, the peculiar physiognomy, hesitating speech, staggering gait and condition of the tongue are met with, an examination should be made for the presence of buboes or of pulmonary disease, and this should be still further supplemented by an examination of buboes, blood and sputum for bacilli. By puncturing the bubo, even at its earliest stage, a small quantity of the gelatinous contents can be sucked out with a sterilised glass pipette guarded at the mouth-end by sterilised cotton wool. If the contents so obtained are then spread on a glass slide or cover-glass, gently heated as in the ordinary preparation of a microscopical specimen, coloured with carbol-fuchsin or gentian-violet, and then examined by a $\frac{1}{12}$ -inch oil-immersion lens, the field will be seen to be covered with coco-bacilli or diplo-bacteria, large numbers of them being more deeply stained at the ends than in the centre. No other disease with swollen glands presents microbes such as these. Their presence is sufficient to arouse the greatest suspicion at any time, and the material ought at once to be taken to a laboratory where the bacilli can be cultivated and the confirmatory tests applied. When plague is known to prevail in a country the discovery of bacilli by microscopical examination, combined with the clinical features,

is sufficient to make the diagnosis of plague a certainty. Should the case come under observation at a later stage when the bubo is softened, disintegrated and in a purulent condition, no bacilli may be found. Then the serum-test can be applied, the blood of a plague patient giving the specific agglutination-reaction to a culture of plague-bacilli. In pneumonic plague an examination of the sputum for the characteristic bacilli is the chief diagnostic test. In the fulminating or septic type of plague, the bacilli early invade the blood, an examination of which will show the microbe. In these cases several blood-preparations should be made. In all doubtful cases a larger quantity of blood should be taken from a vein. Occasionally the microbe is found in the urine, and in the milk of lying-in women.

In the case of the dead body the *post-mortem* appearances and the detection of the plague-bacillus in the primary buboes and the adjacent inflammatory connective tissues or in the blood, spleen, secondarily affected glands, bone-marrow, bile, urine, pneumonic patches, or dropsical fluid of the lungs, establish the nature of the disease.

TREATMENT.—*Curative.*—Good nursing and stimulants will do much for the patient, but the struggle is between the natural powers of the patient and the weakness or virulence of the microbes. Neutralisation of the toxin and destruction of the plague-bacillus without harm to the patient are the rational objects to be aimed at in treating a patient, and these are not obtained by any ordinary drugs. The only known method of attempting to deal with the problem is serum-therapy, and hitherto this method has varied considerably in its results, ranging from comparative success to complete failure. In twenty-one cases in which Yersin's serum was employed in China, the mortality was only 7 per cent. In Bombay it practically failed; while in Oporto out of 142 cases treated with the serum, only twenty-one of the patients died, which is equal to a mortality of 14.78 per cent. Possibly the differences are due to different methods of preparing the serum. The Chinese serum was obtained from the horse after injecting it with living and virulent cultures, but owing to the dangers attendant on this method, the Bombay serum was prepared by injecting dead cultures. The serum used at Oporto was obtained by injecting horses first of all with dead cultures, and then with living and virulent cultures. Greater success was obtained at Oporto when the serum was used in large doses and when employed intravenously. At the beginning of the illness, or as soon as the patient came under observation, an intravenous injection of 20 cubic centimetres of the serum was given, followed by two subcutaneous injections of 40 cubic centimetres each in the first twenty-four hours, and by subcutaneous injection of from 10 to 20 cubic centimetres or 40 cubic centimetres on the next and subsequent days until the temperature fell to normal and, in some cases, even for two days afterwards. Calmette and Salimbein report that no ill results ensued from these injections, further than an occasional erythema and articular pains, which were no more intense after the intravenous than after the subcutaneous injections.

As regards ordinary treatment the best results are obtained from good nursing, early confinement to bed, the maintenance of the recumbent position to

prevent syncope, careful feeding and general treatment to keep up the patient's strength and to prevent complications. To control the febrile symptoms and check delirium, ice-bags to the head, sponging of the body and the use of hypnotics, which are not depressants, are beneficial. To sustain the action of the heart alcoholic stimulants, ammonia, strychnine and digitalis may be employed. Complications are treated on general principles as they arise. The pain and tenderness of buboes are much relieved by the application of the ice-bag, which has also a good effect on the infiltration. Other applications such as glycerine and belladonna and poultices have been found useful. The bubo is opened when pus forms, but nothing is gained by too early incision. With the most careful treatment, however, the mortality varies according to the virulence and type of the disease and the race attacked. The mortality varies from 50 to 95 per cent. of those attacked. Europeans in recent epidemics have had even a lower mortality than 50.

Preventive measures in an infected house.—The precautions to be taken by the physician to prevent the spread of the disease in the family consist in notifying the case to the local authorities on whom rests the responsibility for carrying out the necessary measures to prevent extension from the house. Until the local authorities can take action, or if the circumstances of the case do not permit of removal to the hospital, the patient should be strictly isolated in the most secluded and best ventilated room in the house. A solution of perchloride of mercury (1:500) is recommended as a disinfectant. Sputum, urine, and excreta should be received in vessels containing perchloride of mercury of this strength, while a solution of half this strength may be used in vessels for soaking soiled clothes, disinfecting cups, spoons, &c., or washing the hands of the medical attendant and nurse after handling the patient. Nothing from the patient should be discharged down a watercloset or drain without being thoroughly mixed, and left in contact, with an abundant quantity of perchloride solution, otherwise rats in the sewers may become infected and carry the disease elsewhere. In the event of death, a sheet soaked in the strong perchloride solution should be wrapped around the body, and carbolic sawdust put into the coffin.

Of preventive measures for the medical attendant, the nurse and the relatives who may have close association with the patient, the most important is inoculation with Haffkine's plague-prophylactic. This prophylactic consists of a culture of plague-bacilli in broth which is kept in a state of growth for six weeks, after which it is submitted to a temperature of 70° C. for one hour in order to kill the bacilli. The mixture is then standardised and 2 to 5 cubic centimetres are employed as a dose. Subcutaneously injected into the arm or the flank, it causes in a few hours a rise of temperature to 102° F., sometimes to 105° F., intense headache and malaise and discomfort which usually lasts about 48 hours. At the site of the inoculation a painful swelling appears which necessitates rest for a day or two and remains evident for at least a week. Observations have shown that the inoculations with Haffkine's prophylactic not only sensibly diminish the chances of being attacked with plague, but also if attacked reduce the chances of death. The incidence of plague among those not inoculated has been shown to be in some cases four, five, and

nine times greater than among the inoculated, and the mortality among the inoculated only two-thirds that of the non-inoculated.

General measures of prevention are of two kinds, international and local. The international were formulated at a meeting of the Powers in Venice in 1897. Previous to that time many of the European nations adopted quarantine-rules framed upon those adopted in Venice in 1485. These consisted in the isolation in lazarettos of all persons from an infected port or country, and the detention and disinfection of goods and merchandise by exposure to the sun, for a period at first of 40 days, and later on for a shorter time. The rules were based mainly on merchandise being the principal carrier of the infection. As commerce increased the inconvenience of this system became extremely burdensome, and it became recognised that in the conveyance of disease infected persons were more dangerous than merchandise. Disinfection by steam and other means had also become more precise and could be effected in a few hours. To prevent importation by infected persons it was only necessary to know the period of incubation of the disease; to deal with the sick coming from an infected locality, to disinfect infected articles and to detain or keep under surveillance the healthy during a period which is considered to be the longest for the incubation of the disease. That period has been fixed at the Venice Conference at ten days. Rules were framed regulating these measures for arrivals both by sea and by land. Every Power also bound itself to notify to the others every outbreak of plague and to issue a bulletin weekly. A place is considered infected until ten days have elapsed after disinfection from the last case. Since the Venice Conference two other measures suggest themselves, based on further information obtained about plague. The first is the use of the protective power of Haffkine's prophylactic, and the second is the destruction of rats at infected ports and on the voyage on ships from infected ports, and in countries and localities in much communication with infected places.

The practical application of Haffkine's prophylactic to the crews of all ships and boats, large and small, coming from infected ports would probably largely reduce the danger of the importation of plague. Similarly, under certain circumstances and precautions the protection afforded to passengers or travellers desirous of crossing the frontiers into a healthy country would prove very valuable.

Local measures in an infected locality are based on the facts that early information is absolutely essential, that plague is due to a microbe, that the sick person is infective, that the period of incubation is usually not more than ten days, that the soiled personal linen of the sick may carry the disease, that rats distribute the infection, and that Haffkine's prophylactic is protective. Notification of sickness to the local authorities, isolation of the sick and the removal of the healthy from the infected house until it has been disinfected, and the destruction of all rats are measures of the first importance. For villages and small towns the removal of all the inhabitants on the infected area into camps is a very valuable measure; but for large cities this is impracticable. In such cases inoculation with Haffkine's prophylactic not only of the inmates of the infected house but also of the

inhabitants of the houses around the house, forming a zone of comparatively immune persons, is the most effective substitute.

By the destruction of rats and mice before plague is imported the chances of the disease developing into an extensive epidemic is very much lessened. If this has not been done, it is an essential part of the sanitary measures against the spread of plague that the destruction of rats and mice should be commenced as soon as plague is recognised. A systematic and regular inspection of houses in the poorer quarters and in the neighbourhood of the docks, warehouses, grain-depots, and other buildings which are likely to contain rats, is necessary. The measures of destruction are to be directed not only to the locality in which the rats are dying but also to the adjacent localities, and the disposition of the rats to migrate is to be borne in mind in order that on the first appearance of this phenomenon the rats coming into a healthy locality may be destroyed. Dead rats should not be removed until boiling water, carbolic acid or corrosive sublimate is thrown plentifully over their bodies to kill infected fleas on them which are liable to convey infection.

W. J. R. SIMPSON.

PLESSOR (πλήσσω, I strike).—A hammer-like instrument used in percussion, for striking the surface of the body, either directly or indirectly. See PHYSICAL EXAMINATION.

PLETHORA (πλήθω, I fill).—Fulness of blood. A condition in which the vessels of the body generally, or of any part, are over-distended with blood. See BLOOD, Morbid Conditions of; and CIRCULATION, Disorders of.

PLEURA, Diseases of.—The serous membrane which lines each cavity of the chest, and is so reflected as to cover the lung, is not infrequently the seat of disease. As in its anatomical and physiological relations, so also in its diseases, it presents analogies to the lining membrane of a joint. Its diseases may be of external or of internal causation. They may be considered under the following headings:—

Pleura, Injuries of, p. 1268.

Pleura, Inflammation of, p. 1268.

Pneumothorax, p. 1282.

Pleura, Dropsy of, p. 1285.

Pleura, Hæmorrhage into, p. 1286.

Chylothorax, p. 1286.

Pleura, Morbid Growths in, p. 1286.

Pleura, Surgery of, p. 1286.

1. Pleura, Injuries of.—These may be caused in several ways: (1) by blows upon the chest—and in this case there is usually at the same time an injury to the lung-tissue, the effects of which may overshadow the pleural lesion and its results; (2) by direct wounds with a knife or blunter instrument, or a bullet; and (3) by fractured ribs. With the surgical aspect of these cases we are not now concerned; the pleural consequences may be gathered from the following paragraphs.

2. Pleura, Inflammation of.—SYNON.: Pleurisy; Fr. *Pleurésie*; Ger. *Pleuritis*.

Pleurisy is defined as an inflammation of the pleura, of whatever nature and extent. Clinically and pathologically, pleurisy is the most common of the serous inflammations, and differs only in its accidents from inflammation of serous membranes elsewhere.

ÆTIOLOGY.—The causes of pleurisy, if local, may be obvious enough; if general, not so obvious. Of local causes the chief are wounds or bruises of the chest-wall; fracture of the ribs; caries of the spine; aneurysm; escape of irritating matter into the pleural cavity, whether from the costal side as in peritonitis or osteitis, or from the pulmonary side as in tuberculosis and in disease of the bronchial glands, or from the side of the abdomen as in gall-stone, hydatid, renal stone, ulcers, subphrenic abscess and the like. Foreign bodies, again, such as bones or coins from the œsophagus or larynx, have been known to find their way into the pleural cavity. Acute pleurisy, the result of local causes, is usually more or less proportioned to these in its severity and duration; pleurisy of general or systemic causation, on the other hand, though less regular in its career than pneumonia, has a certain uniformity. The general or systemic causes of pleurisy are now far better known. Between the ages of twenty and forty at least two-thirds of them are tubercular. That the majority of cases of acute, as well as of the more latent pleuritis (p. 1273), are tubercular is proved (1) by large injections of the serum into guinea-pigs (20 c.c. the first day, and as much again, freshly drawn off, on the second); (2) by cultures on peptone-jelly containing blood; (3) by tuberculin after the fever has fallen, or in apyretic intervals; (4) by Courmont's agglutinin-tests (p. 723), wherein the pleuritic serum of tuberculous cases is said to be more effectual than the blood-serum. In children the pneumococcus is often the cause, and sets up pleurisy without recognisable pneumonia. A chill may be the immediate cause of acute pleurisy; but chill must be associated with other factors. A rheumatic or gouty habit is suspected in some cases, and probably with good reason; in a few the influence of syphilis has been recognised. The depression of over-work or harass, the debility of previous illness, and the poison of malaria, are among the contingencies which enable this microbe or that to get a hold; and of these latter causes the B. tuberculosis is the most common. Tuberculosis confined to the pleura is the least menacing and the most curable of its manifestations; but the patient must be watched for some years afterwards. Acute pleurisy often occurs as a part, or as a complication, of other diseases. Thus in acute pneumonia it is rarely absent, and may run on, especially in children, to empyema; and in this, or in a serous effusion, the pneumococcus may be found, or its toxins only may have entered the cavity. It occurs, as cardiac valvulitis and pericarditis occur, in acute rheumatism, but less frequently. Rheumatic pleurisy is very acute, is apt to be bilateral, does not run to large effusion, and is of no long duration. Acute pleurisy following scarlatina is usually dependent upon a rheumatic or nephritic sequel; if it arise otherwise in this malady the pleurisy more often tends from the outset to empyema, as it does in typhoid fever also. Pleurisy arises sometimes after influenza and after measles, when it is probably due to infection from the lung; and, with or without obvious pneumonia, after enteric fever, when Eberth's bacillus may be found in the effusion. Not a few cases of empyema due to actinomycosis are on record. Pleurisy is also, like pericarditis, no uncommon consequence of disease of the kidneys, or of arterio-sclerosis of Bright's disease; when the effusion may be either dropsical or the product of a pleuritis. In septi-

cæmia and in pyæmia a low pleurisy often arises, as like effusions arise in the joints, and may be equally or more latent; or, again, it may be caused by the rupture of a pyæmic abscess of the lung or of a caseous gland into the cavity. The origin of the pleurisy in puerperal and other septic peritonitis is by way of the lymph-channels between the diaphragm and the pleura; and its supervision in some cases of abscess of the liver may receive a like explanation, though in others the passage is direct, by ulceration. Reversely, septic pleuritis may extend sometimes, though very rarely, from the pleural to the peritoneal cavity. Furthermore, a septic pleurisy may arise directly in a person exposed to insanitary conditions, when it is often preceded by sore-throat; such cases often lead rapidly to sero-purulent effusion, and are of the graver kind. Empyema as a secondary suppuration may appear alone; for instance, in such conditions as otitis media. Actinomycosis must not be overlooked, it is probably a more common cause of pleurisy and empyema than we are quite aware of. Acute pleurisy, when 'idiopathic,' is more often on the left side (three to two), and is rarely bilateral. When due to such infections as acute rheumatism or nephritis, it may be bilateral, though rarely of equal severity on the two sides.

Acute pleurisy is common at all ages; it is recorded often within the first six months of life; in babies it is easily overlooked unless there be abundant effusion, and not rarely even then. In children the symptoms are often very latent, neither cough nor pain being manifest, or pain may be referred to the abdomen; moreover, on account of the great mobility of the parts, there is little obvious displacement of viscera: yet pleurisy is really more common under one year than between the ages of two and five years. At the age of five it is frequent, but it reaches its maximum frequency in middle life (æt. 35-45). The younger the child the more readily the effusion becomes purulent; it is more often pneumococcal than in the adult. In many cases the suppuration extends to the pericardium, but this is more common perhaps in older children. Some pleuritis, of course, may often result from extension of pericarditis, but it is usually unimportant. Cases of simple inflammatory pleurisy have been recorded in persons beyond threescore years of age; but in aged persons it is rare, and presents little reaction or pain. The male sex is more often affected than the female, in the ratio of about seven to five; the difference may be due to the greater exposure of men to changes of weather; pleurisy is often said to vary in prevalence with pneumonia, and to be most frequent in April. With the advance of our knowledge of the subject, however, the number of cases of pleurisy attributed to 'chill' is growing less and less, while the class of tubercular pleuritis, favoured by chill or other depressing conditions, is receiving larger and larger accessions. Under one form or another pleurisy is credited with about 2 per cent. of the deaths in England, and with about 1 per cent. of the deaths of patients in public hospitals.

MORBID ANATOMY. (By Dr. Sidney Martin.)—The anatomical characteristics of inflammation of the pleura do not differ from those of inflammation of the pericardium or peritoneum, with the exception that purulent inflammation is more common than is the case with the pericardium.

In *acute dry pleurisy* the surface of the membrane

is congested, and may show ecchymoses; while on the surface is a false membrane composed of fibrin entangling leucocytes. Some slight effusion no doubt occurs, being the liquid left after the coagulation of the fibrin with the plasma. As a rule, red blood-corpuscles do not exude in any considerable number. Proliferation of the pleural cells occurs, with the formation underneath of granulation-tissue, containing new vessels. The costal pleura, as a rule, is affected sooner and more severely than the visceral. Acute dry pleurisy may resolve without adhesions being formed to any extent. When, however, it occurs between the lobes of the lung, adhesions commonly result. The formation of adhesions—that is, of fibrous tissue binding together two layers of the pleura—does not differ from the formation of fibrous tissue, as the result of any other form of inflammation. The fibrin is absorbed, and the leucocytes for the most part disappear. The fibrous tissue is formed from the fibroblasts of the granulation-tissue, which, with the new vessels, is derived from the permanent tissue beneath. In the process of healing of dry pleurisy some account must be taken of the causes of the inflammation. Thus, in non-tubercular pleurisy, the events are as above described; but when the disease is tubercular a greater thickening of the layers of the pleura occurs, and adhesion almost constantly results.

Pleurisy with effusion is another phase of inflammation of the pleura. All the features of dry pleurisy are present, but, in addition, the cavity contains a greater or less amount of liquid effusion. The amount of this varies considerably. It may be as large as 100 or 150 ounces. The fluid sometimes contains floculi of fibrin, or meshes of fibrin may traverse the fluid as it lies in the pleural cavity. When withdrawn during life the fluid is yellowish or slightly green, alkaline, and with a specific gravity usually between 1016 and 1023. Microscopically, it contains a few leucocytes, some endothelial cells derived from the pleura, and a few red corpuscles. The leucocytes and endothelial cells are frequently swollen. The fluid usually coagulates spontaneously after removal during life, forming a soft gelatinous clot. The coagulation either occurs at once, or may take several hours. It is hastened by the addition of blood. The average composition is as follows: 3·5 to 5 gr. per cent. of albuminous substances, 1·5 to 3 per cent. consisting of serum-globulin, 1 to 3 per cent. of serum-albumen, and 0·02 to 1 per cent. of fibrin. The extractives present are chiefly sugar and cholesterin; but urea, uric acid, leucine, and tyrosine have also been found. *Hæmorrhage* may occur in a pleuritic effusion, due either to the tubercle-bacillus or to one of the other bacteria causing the disease. The fluid removed by the aspirator is distinguished from pure blood by its watery character, and by its specific gravity, which is lower than that of blood. In acute cases the blood is slightly darker in colour, but differs from the blackened bloody effusion observed in some cases of malignant disease of the lung. *Purulent effusion, or empyema*, is a specific result of certain of the micro-organisms causing the pleurisy. The anatomical changes in the pleura are practically the same as previously described, but the fluid which is exuded contains an enormous number of the leucocytes characteristic of pus. These are chiefly the polynuclear neutrophile leucocytes, and are seen in various degrees of degeneration. The character of the purulent effusion varies

in different cases, from a serous effusion containing an excess of leucocytes, whereby it is made turbid, to a thick creamy pus of a slightly greenish tint. The *process of repair* in pleuritic effusion takes place first of all by the absorption of the liquid effusion; subsequently by the changes which have been previously described as occurring in dry pleurisy. Adhesions commonly result, and retraction of the side of the chest, due mainly to the inefficient expansion of the lung. When the pleuritic effusion is tubercular in origin, great thickening of the pleura results during repair, and a greater retraction than in non-tubercular pleurisy. In empyema repair occurs after the pus has been evacuated, though it is possible, from the occurrence of calcareous plates in the pleura, that a small collection of pus, usually tubercular in origin, may be absorbed, and repair take place, without its being evacuated. In repair of empyema after an opening has been made in the chest, great thickening of the pleura results, owing to the abundant granulation-tissue that is formed, and complete repair may not take place for many months or not at all, a sac being left exuding a small quantity of pus from greatly thickened walls.

Putrid effusion and empyema occur by direct infection from the lung (as in cases of gangrene or pneumothorax); when the pleura communicates with the œsophagus (as in cases of cancerous stricture); when the empyema results from a subphrenic abscess; and in some cases of septicæmia, with infarction of the lung.

In cases of large effusion the lung is found compressed, and often bound down by false-membranes extending from the walls of the cavity. In adults the lung is usually found in the space between the vertebræ and scapula; it retracts primarily by its own elasticity, withdrawing itself upwards, inwards, and backwards, and may be compressed to one-quarter or even one-eighth of its normal volume; it is then flattened, leathery, bloodless and airless, and will sink in water. In recent cases as the pressure subsides, the lung may, and generally does, recover much of its former volume; and it is surprising how fully the lung may re-expand in spite of false-membranes, bands, and prolonged compression. Nevertheless, either complete or partial adhesions or bands of connective tissue generally remain indefinitely after acute pleurisy; and for the most part do no direct harm. If the lung fail to re-expand to any extent, the deficiency is made up by the falling inwards, partly of neighbouring soft parts, and partly of the chest-wall. But on the other hand, false-membranes and bands as well as the fettered lung are, or may become, the seat of degenerative processes, and especially of tuberculosis and of fibrosis. During empyema the contact of pus promotes ulcerative and septic changes in the lung, as it may do likewise in the vertebræ, ribs, and other neighbouring parts. Thus the pus, finding for itself a passage in the direction of least resistance, may pierce lung or thorax, and establish a pulmonary or costal fistula.

Subpleural ecchymoses, though often accompanying evidences of inflammation, are not always caused by pleurisy. They occur in deaths of children after broncho-pneumonia and diphtheria; but there is usually a patch of pleuritic inflammation upon and co-extensive with them. As the punctiform ecchymosis of Tardieu, they may also be found on the heart, pericardium, and thymus

glands, and are not by any means peculiar to deaths by pleurisy; but are probably always associated with obstruction to the entrance of air into the lung.

In all cases the position of the heart and other viscera must be observed, and the chambers of the heart, the pulmonary artery, the inferior vena cava, and other vessels examined for clots. In empyema a careful examination of the body for secondary abscesses must be made, not forgetting the brain.

CLINICAL CHARACTERS AND VARIETIES.—For mere convenience pleurisy may be divided into six varieties, as follows: (α) *Dry*; (β) *Acute*; (γ) *Diaphragmatic*; (δ) *Quiet, with large effusion*; (ε) *Tubercular*; (ζ) *Fibroid*. Each of these requires separate consideration. Effusion, when present, may be serous or may be purulent, or a serous effusion may change into a purulent; but since antiseptic precautions in operative procedure have been perfected, this perversion comes more rarely under observation.

(α) **Dry Pleurisy.**—This is so called not because it is attended by no effusion, but because the effusion is so slight as to escape notice. Usually, it results in an adhesion of the opposite surfaces of the membrane. It may not be revealed by any sign or symptom during life. Adhesions, more or less extensive, due to this process, are very often found after death. Dry pleurisy may occur alone, or as a complication of irritative changes in neighbouring tissues, as in the lung or chest-wall. It is common in Bright's disease. It is rarely absent from the surface of an infarct, and may give rise to substantial and recurrent effusion of an aseptic kind. Such is the obscure origin of many a pleurisy in elderly persons. Pain or pyrexia, more or less fugitive, may accompany dry pleurisy; but in many cases they pass unnoticed. Should attention be drawn to the chest, friction may generally be detected at some stage. An obscure pain in the chest or loin, or a frequent teasing dry cough, may at times be traced by the close observer to a patch of dry pleurisy in some part of the chest. A friction-sound due to such a patch may be transient, or may be audible for many weeks. Dry pleurisy, as such, is not revealed by radiography. It is supposed that some of the pains in the chest which accompany phthisis are due to the intercurrent of dry pleurisy; but they are as frequently myalgic (from cough) or neuralgic. On the other hand a friction-sound, as in the upper scapular area, may be the first sign of tubercular infection, and not infrequently of a rapid case. Dry pleurisy, with its resulting adhesions, is rarely directly injurious; indeed, it is rather a safeguard when any destructive process, such as phthisical ulceration, threatens to bore into the pleural cavity. If it fail, and morbid matters escape into the cavity, acute pleurisy and pneumothorax are the probable consequences. Dry pleurisy often ends in but slight thickening, the two pleural surfaces adhering without much increase of substance. In other cases the thickening may be considerable, but this probably would indicate some more persistent irritation, such as we find, for example, in those dense coverings which often invest the apex of a lung in chronic phthisis. Tuberculosis apart, the remoter consequences of dry pleurisy are rarely of importance. In some instances it may limit the chest-movements, or may tie the parts so as to cause transient pains, described as dragging or tightening. Such pains are usually referred to the

sub-axillary or sub-mammary regions, and may be really annoying; more often they do harm by ministering to needless fears. A generally adherent lung is usually retracted, and is more liable to tubercular disease, active or fibrous. It is said that in rare cases hypertrophy of the heart has resulted from embarrassment of its action by pleural bands. Dr. Bowditch told the writer that he had seen this result twice at least.

It is useless to prescribe treatment for a disease which escapes observation, or is but a secondary event in the course of more serious processes. Where dry pleurisy is found, and is doing harm by exciting cough or otherwise, the best practice is to place two or three light blisters in succession over the affected part, and to watch the patient closely, especially his temperature and his urine.

(β) **Acute Pleurisy.**—Acute pleurisy generally appears as an important illness. In the large majority of cases it is unilateral, and perhaps never are both sides attacked simultaneously. Bilateral cases are rheumatic or tubercular. It sets in with fever, pain, embarrassment of the breathing, and cough—sometimes catarrhal, usually reflex. These symptoms bear no certain proportion to each other. The fever has no very characteristic type, but is what is known as a symptomatic pyrexia. Speaking generally, a rigor of onset would indicate pneumonia, but there is often a succession of lesser chills. Nor are there any very definite stages of increment, but rather a daily fluctuation of remittent, more rarely of intermittent type, with evening rise; the elevations not often reaching and rarely exceeding 40° C. (104° F.). Peter stated that the temperature of the affected side is higher by 1°–3° F.; falls with effusion, but rises again if this become purulent. At first the blood-pressure is high, the pulse being small and hard; after the first onset the pressure falls, and the pulse becomes dirotic. A quick pulse is characteristic of pleurisy in most of its forms, even if there be no fever; for it is by this frequency rather than by more powerful contractions of the heart that blood-pressure is kept up fairly well even when large pulmonary areas are restricted, or the auricles compressed. The arterial pressure therefore should be closely watched in cases of copious effusion. In severe cases the difference of pressures in inspiration and expiration may be very perceptible, and occasionally the pulsus paradoxus has been recorded. As the effusion reaches its height, the fever in acute pleurisy gradually recedes, unless the case approaches to the form (δ); and the fever may subside, may fluctuate, or may drift into hectic. The pain is often very characteristic, but at other times is variable, and even delusive. Most commonly it appears as a stitch in the side, about the level of the false ribs, which is intensified by inspiration and cough. The deep breath when partly drawn is cut short, as if with a stab, while the face of the patient is wrung with an expression of sudden distress. Such inspirations are, however, instinctively avoided, and may have to be called for by the physician, so that the face may speak rather of apprehended than of actual suffering; in either case the expression is a telling one to the practised observer. The fixed *alae nasi*, which are dilated but do not oscillate as in some other kinds of dyspnoea, the parted lips, the bright eye of fresh fever, the cheeks flushed but not congested as in pleuro-pneumonia, the preoccupied and apprehensive expression, the posture semi-erect,

slightly bent forward and toward the affected side, the shallow breathing, the fixed chest, the hand on the side, the curt speech, the stifled dry cough, make up a clinical picture often seen, and easy of recognition. It is a curious fact that these symptoms of distress are generally more marked in a robust patient, or one previously healthy, than in the weakly, ailing, or cachectic. The pain, however, may wander from the lateral or antero-lateral aspect of the lower ribs, and appear in the hypochondrium, or even on the opposite side. At other times it may become more diffused, and play upon the brachial plexus, darting from the clavicular and scapular districts to the upper chest, shoulder, or arm. This radiation is more common in the diaphragmatic variety (γ). In some bad cases of empyema the pain is very distressing and prolonged. Severe abiding pain in a case of pneumonia is suggestive of purulent pleurisy. Whatever the treatment, we look for some relief of pain, cough, and conscious dyspnoea on the third or fourth day. The respirations, however, may still range above the normal rate, from the mechanical interference of increasing effusion, or of this increase combined with oedema of the open parts of the embarrassed lung, and perhaps of its overworked fellow. About the end of the week, be it more or less, the pleurisy has run its course, and, in favourable cases, the effusion has attained its maximum; the urinary, gastric, and other glands regain their normal activity; and convalescence, with absorption of the exudation, is to be looked for. If in three weeks signs of considerable effusion remain, the case is passing into a chronic form. Thus far, then, the disease is painful rather than dangerous, death in the first week of ordinary acute pleurisy being practically out of the question. Malignant cases of pleurisy, however, occur, in which the temperature may be 40° or 41° C. (104° , 105.4° F.), the pulse reach 140, the tongue become dry and brown, the prostration be excessive, and the exudation run promptly to pus—pus which may be fetid, although without obvious reason. Except as complications of septic and other diseases, such cases are rare, and even after free evacuation of pus by incision, they are too often fatal. An important instance of recovery from such a case has been reported by Gairdner and Buchanan. By certain signs in the chest we know the height to which the effusion has flowed in the cavity, and we await its ebb. Usually, in a day or two, some fall is noted, and in favourable cases this ebb runs quickly at first, and afterwards more slowly as the products become denser. The false membranes undergo fatty degeneration and slowly vanish, though some remnant is usually to be detected for an indefinite time after the patient is about. If the pleura thickens much, as it frequently does, the signs of it may be carried to the grave. Probable as is the favourable result in strong persons, yet it is not to be too lightly promised even to these. Too often when we are awaiting the ebb we find a new flood, the level of the fluid rises into the upper chest, and the patient, who hitherto has lain on the sound side to avoid pain, turns on the affected side to give full play to the open lung. This flow may recur with or without renewed fever, but is generally attended by a proportionate increase in the rate of the pulse, and diminution of its volume and pressure. These events are more common in streptococcal infection. Coincident with the diminution of blood-pressure

is a diminution of the urine, which, probably, had become more abundant as the fever ceased. That the changes, both of pulse and urine, depend upon the effusion is shown by the rapid recovery of both when fluid is artificially let out from the pleura; the pulse then falls in rate and increases in tone under the finger, and the urine soon becomes more abundant. A little albumen is sometimes present during the time of pulmonary obstruction (see ALBUMOSURIA). Under ordinary circumstances a renewed flow of urine is indicative of pleural absorption; but the case may pass on into the form (δ), or into an empyema. It is hard and often impossible to tell when the full chest contains serum and when pus. Hectic fever may exist with serum, but if with fever be associated tenderness or subcutaneous oedema of the affected side, change of countenance, loss of appetite, wasting of flesh, failure of strength, thrush, diarrhoea, or any of them, and the more if there be any inherent constitutional frailty, a preceding acute specific fever, or a septic infection, we must fear that tuberculosis is present, or the fluid turning to pus. In the later weeks or months of an acute pleurisy which has not ended in resolution, death may threaten, and may not be averted. In some cases, as after scarlatina or pneumonia, and especially in young children, the effusion may be purulent from the beginning, and a fatal result may be feared even in the earlier days of the malady. Under ordinary circumstances, however, in healthy persons who have been carefully treated from the outset, and who have not been exposed to septic influences, we expect to have to deal with an effusion moderate in quantity and stable in quality, which rarely remains at its height more than two or three days; and in three weeks should be largely absorbed. We shall not therefore be too ready to tap in such cases. In other cases again, happily rare, acute pleurisy, with remittent fever, continues for many weeks. Effusion in these cases may not be very rapid, but recurs gradually after the removal of moderate quantities; or it may not seem to need removal. The signs are simply those of acute pleurisy, but resolution does not take place, or is indefinitely deferred. Death may result or the patient may slowly recover. After death may be found evidences only of active simple inflammation, compression of the lung, and sero-fibrinous exudation. The other side, and the rest of the body, may be quite healthy. To these cases the name *relapsing pleurisy* might be given; of those which are not tubercular, the specific nature is unknown. When inflammation falls upon both pleurae, it generally falls also upon the pericardium, and such cases are terribly dangerous. Even if moderate in degree in each part, yet taken together the embarrassments of the patient become very grave, and death may be imminent. It is important to give relief by puncture, pleural at first at any rate, as early as possible. A purulent pericardial effusion may attain great dimensions, and if it be associated with pleurisy, and the case be not seen early, or not followed during its course, diagnosis of it may be impossible. The probability of the association must not be forgotten.

(γ) **Diaphragmatic Pleurisy.**—Diaphragmatic pleurisy is not essentially different from the preceding, but the symptoms are often peculiar. If the inflammation be, as it may be, confined to the diaphragmatic area, then the ordinary physical

signs of pleurisy with effusion are either absent, at any rate at first, or so ill-marked as to puzzle the inexperienced practitioner. The onset may be as acute as in ordinary pleurisy, but the distress is greater and more alarming. The practitioner is surprised and perplexed to find a person, in whom he can discover no important organic defect, in an agony as it were mortal. The presence of pain shooting from the lower ribs of one side suggests pleurisy; but the ribs on both sides play with perhaps more than normal freedom, and no physical signs may be audible, unless it be that the practised ear may detect a want of breath-murmur at the base of one lung, and, after the first day or two, it may be, two finger-breadths of dulness there. Still no friction may be heard, and it seems impossible at first sight to associate signs so slight with clinical phenomena so alarming. For the patient may be as one having a clot in the heart, or a sudden perforation of the pleura, so terrible and so absorbing is the strife for inspirations which never satisfy, so keen the dread of any handling which may interfere with the one permanent need of sitting erect, and of keeping the upper respiratory muscles in full play. These inspirations may range from forty to fifty in the minute, or may even run with the seconds, except only when cut by a hiccup or a heaving of the stomach. To this are added the suffering of pain which shoots through the waist to the back, or darts round the shoulder-blade and collar-bone into the shoulder, and a sense of a fatal grip. There may be tenderness round the insertion of the diaphragm on the affected side, and perhaps in the course of the phrenic nerve over the anterior scalene muscle. The normal character of the heart's action gives confidence to the physician; abdominal breathing, however, is lessened, sometimes on the affected side only, and any pressure upwards upon the diaphragm is resented. All these symptoms finally lead to the conclusion that acute inflammation has partially attacked and so far paralysed or inhibited the diaphragm, without extending on to the pleura above; but the diagnosis is of course the easier if pleurisy be discovered elsewhere in the chest. A patient thus attacked seems to be in no little danger, but recovery may be anticipated if there be no mischief below the diaphragm. Fortunately the malady, thus circumscribed, is far less common than ordinary pleurisy, and indeed may be called rare. As stated above, however, inflammation of the diaphragm may complicate ordinary pleurisy, and produce both the pains in the brachial plexus and the excessive and paroxysmal dyspnoea. An empyema or other effusion lying between the diaphragm and the pleura, as also between the lobes of the lung, may be out of reach of direct diagnosis (unless the needle be used), and may have an obscure commencement. A persistence of fever, especially if hectic in character, would dictate very searching and suspicious examinations of the patient and the repetition of exploring operations so long as any doubt remains. Diaphragmatic pleurisy may arise in inflammatory diseases of the liver or spleen, or of neighbouring parts of the peritoneum. If peritonitis extends, as it not infrequently does, through the diaphragm, it may set up mischief in both pleuræ. But, perhaps because of some special activity in the liver and its capsule and ligament, it comes through more frequently on the right side. In all such cases the base of the chest must be examined re-

peatedly. In cirrhosis of the liver pleuritic effusion is prone to appear, and may be hæmorrhagic, even when the peritoneal fluid is not so. It is because of subdiaphragmatic disease that the death-rate of diaphragmatic pleurisy is so high. See DIAPHRAGM, Diseases of, p. 387.

(δ) **Quiet Pleurisy with Effusion.**—This form of pleurisy is often regarded as the sequel of acute pleurisy; but if we except the cases in which pleurisy, at first sthenic, afterwards follows the asthenic tendencies of the patient, and those in which acute pleurisy has been treated with neglect, we shall find that this form begins not sharply but quietly, and is indeed often unnoticed until the chest is laden with fluid. If the patient suffered pain it was too slight or too indefinite to ensure attention; the fever, unmeasured by the thermometer, escaped observation; the chest, slowly invaded, accommodated itself to circumstances until the fluid had nearly filled the cavity; and the patient may only have sought advice because of dyspnoea on ascending hills or stairs. A quick eye may detect in him an expansion of the *alæ nasi*; or, indeed, may see that the patient is breathing at double, or nearly double, the normal rate; or at the outset a sensitive patient and a vigilant physician may fully perceive the remittent—almost intermittent—fever, the indefinite pain and the encroaching effusion, and may lessen the evil by timely interference. As a rule, where effusion is large the patient lies on the affected side, thereby escaping the pressure of the fluid upon the mediastinum, and enabling the sound lung to have free play. This decubitus is not invariable, and is avoided if the affected side be painful. With pyogenic change in the effusion the patient may turn off the affected side, as this change is sometimes accompanied by a renewal of tenderness to pressure. When the effusion has come on very gradually, the patient is often able to lie on either side indifferently, and indeed to walk about. Occasionally a large pleural effusion may cause some dysphagia. Let the reader then remember that pleurisy running on to large serous effusion is very often quiet in its approaches; and, if in our examination we are content with raising the patient's shirt in front, it may be overlooked until matters become extreme. Even if the effusion be purulent, its accumulation may be equally rapid or equally silent; being silent when it is the further change of a serous effusion, being silent and rapid when it comes as pus almost, or quite, from the outset, as in septic and infectious diseases, and in children. If acute pleurisy drift into chronic pleurisy, which after the lapse of a month without absorption may be said to be the case, the fever, which may have vanished for a while, lights up again fitfully at times, and fresh attacks of inflammation take place in the pleura and in the new membranes. With this there are also renewed outpourings of serum, which sometimes increase so rapidly as to put the patient in imminent danger of death by syncope. The fever in these stages is often hectic in character, so that the presence of hectic alone does not prove the effusion to be purulent. Quiet effusive pleurisy is very uncertain in duration. Should the effusion be not excessive, and remain serous, months may elapse—nay, even years—before it is absorbed; and the absorption may be gradual, or may be deferred for awhile, and then completed more quickly. It is needless to say that even so favourable a result as this cannot do away

with the injury which the chest must suffer from being waterlogged for so long a time. It is well known that a lung thus compressed is very prone to become the seat of tuberculosis. Very frequently, however, the effusion is sero-purulent or purulent, even from the beginning; and if left to itself finds an exit gradually by many minute ulcerated spots through the spongy lung, and so is expectorated gradually; or, by an opening into a bronchial tube, rushes with a sudden and copious discharge into the mouth. The expectoration in the former case, if profuse, is usually inoffensive, and muco-purulent; in the latter, the gush of pus, often stinking, is sometimes so great and so sudden as to swamp the lungs and threaten or even produce suffocation, especially if it occur during sleep. In the latter case we have usually to deal with a subsequent pyopneumothorax, which, if left to itself, may ultimately heal, but is as likely to end in death by slow hectic and marasmus. The issue is scarcely more promising if the pus find its way outwards between the ribs; and this it may do by a direct opening, usually in the fifth space towards the front, or by a sinuous opening: or it may gather between the ribs and skin, forming there a large superficial abscess—'*empyema necessitatis*'—the tension of which varies with respiration and increases with cough, and this of course more or less readily as the communication is more or less direct. These changes in tension aid us in distinguishing such issues of the pleural cavity from local abscesses of the chest-wall. In pleuritic effusions pressure is rarely negative, often highly positive, being high in young elastic chests, with large effusions, low in old persons and with small effusions. The chest in cases of spontaneous opening is imperfectly emptied; the issue is not in a good position, and septic poisoning is hardly prevented; yet a lingering illness is by no means always to be cut short by operation. Or the pus may find its way into the opposite pleura, thus doubling the empyema, and even such patients have recovered; or into the pericardial or peritoneal cavities, though such terrible events are fortunately very rare; or it may burrow between the tissues and appear at distant places, and thus may mimic psoas or other sinuous abscess. A cure of empyema by reabsorption is said to be possible, but, except in the case of small encysted collections, the possibility must be a bare one.

In some cases the fluid may rise in twenty-four hours from the angle of the scapula to the clavicle—an obliteration of breathing-space far more perilous in its rapidity than a more gradual one to which the system slowly adapts itself. Pleurisies with large effusions have no definite course, for, even if serous, absorption is difficult, and so far as it occurs is too often compensated by renewed febrile movements, with renewed effusions.

(e) **Tubercular Pleurisy.**—In considering the relations of pleurisy to tuberculosis we have to deal with four classes of cases: (1) Those in which the pleurisy is tubercular in its origin and development. (2) Those in which one or more attacks of pleurisy, not known to be tubercular, have preceded phthisis. (3) Those in which pleurisies spring up here and there in the course of pulmonary phthisis. (4) Those in which tubercle arises in the exudations of a pleurisy supposed to have been simply inflammatory.

These states may be considered reversely, beginning with the last. Tuberculosis is a far more

frequent cause of pleurisy than 'chill,' or the 'rheumatic' infection; but, apart from tubercle in other parts, rarely destroys life directly, and is not often found alone upon the *post-mortem* table. Tubercle, however, often betrays its presence in the pleura before it manifests itself elsewhere, so that the occurrence of pleurisy should always excite suspicion, and this the more if patches of it spring up here and there without much resulting effusion. As in the peritoneum, tubercular inflammation may cause large effusion, or may be of the more adhesive kind; and many sero-fibrinous or sero-purulent pleurisies are of tubercular causation, direct or indirect; the fact of recovery by no means proves the non-tubercular nature of the case. No difficulty arises in deciding upon the nature of intercurrent pleurisies in pulmonary phthisis, though often these are not tubercular in a strict sense. The difficulty is to detect tubercle in a pleurisy apparently primary and simple, which appears to progress towards recovery, or often, indeed, to reach it. On the other hand the temperature, if it has fallen, may rise again fitfully, and the pulse quicken, yet without much evidence of empyema or of any returning effusion. Then a patch of pleurisy on the other side, or a sign of mischief at the apex of a lung, may betray the character of the relapse, and in the pleura, or the false-membranes, are the caseous or softened residues of the first crop. Most difficult of forecast are the pleurisies of the first class, which, however painful or profuse, end in recovery which seems complete, and is no doubt often permanent. But such convalescents should for years to come, or for life indeed, beware of depressing causes, which might re-awaken the disease. For the temperature may begin to be hectic; a short dry cough occur; signs of phthisis appear in the lung; and the end come in the too familiar way. The tubercle-bacillus is very rarely found in the products of pleural paracentesis, save indirectly by inoculation-experiments; in most cases it is enclosed in the granulations. But for some reason or other tubercular effusions are apt to be malodorous, and when purulent are insidious and tedious. The physician must then regard with anxiety and precaution all pleurisies, however frank in attack, however happy in their resolution, or however free the subjects may seem to be from any taint or character of consumption.

(f) **Fibroid Pleurisy.**—Sometimes as a primary affection, but more often as an ultimate consequence of an acute pleurisy, the membrane slowly thickens, and, allying itself with a like overgrowth of the connective elements of the lung, increases at the expense of the proper pulmonary tissue; and, gradually contracting after its kind, stifles and destroys a great part of this organ. Fibroid pleurisy generally begins at the base, and the visceral layer may increase until it may form a dense leathery covering even one-third of an inch in thickness. Tuberculosis is generally, perhaps always, concerned in the process, but may be difficult to detect, even after death. See LUNG, Cirrhosis of, p. 909.

Hæmorrhagic Exudation.—Pleurisy may be attended by hæmorrhagic exudation—that is, by exudation mixed with more or less blood, the loss of which may be exhausting—even in some cases of empyema. These cases, though sometimes very acute, are usually chronic; the hæmorrhage depends on bleeding of the new vascular tissues, and, moreover, may be aggravated by some other

abnormal state of the patient, such as scurvy, carcinoma, arterio-sclerosis, or tuberculosis. It seems probable that hæmorrhages do not suppurate unless micro-organisms gain access to them, and tend to do well if other conditions are favourable. A small quantity of blood may give to a body of serum a sanguineous hue, but the specific gravity would remain low. After paracentesis a hæmorrhagic may quickly pass into a clear serous effusion.

Pneumothorax.—This is a term applied to that condition in which, owing to perforation into or from some open channel, air finds entrance into a cavity, which is or becomes emphysematous. At the same time pus is evacuated. The lung may in measure re-expand, or in neglected cases may be irrecoverable; the chest-wall falls in more or less, according to the rigidity of the ribs and other conditions in the case. On the entrance of air dullness gives way to clearer and lower notes, except in dependent parts still occupied by effusion; and the pitch will vary with the thickness and density of the false membranes within, and the degree of pulmonary expansion. See LUNG, Perforation of, p. 936; and section 3, Pneumothorax.

PHYSICAL SIGNS.—Throughout the stages of pleurisy inspection may tell us that the movements of the unaffected side are excessive, especially if compared with those of the affected side which hang back, either by the warning of pain indirectly, or directly by effusion which stops the play of the lung. This laggard movement is often to be noted also in the abdomen on the same side, especially in diaphragmatic pleurisy. As the effusion increases the chest may or may not be seen to bulge beyond its true lines; the intercostal spaces are usually, but not always, flattened up to the level of the ribs, and the form of the affected moiety of the chest becomes more cylindrical, as is best shown by the cyrtometer. The xiphoid cartilage is often displaced away from the side affected, to right or left of a string stretched from the manubrial notch to the symphysis pubis. The diaphragm may be so thrust downward and forward as to cause a fulness in the epigastrium, and a slight depression of liver or spleen; with large effusion there may be bulging even of the supraclavicular space; and the outline of the affected side measured on the transverse submammary line will usually measure more than on the healthy side. Half an inch is an important difference, seeing that in a young adult the other and healthy side in overwork expands about half an inch or more beyond the normal, and will fall again as the compressed lung expands after paracentesis. The right side of the chest in health is usually larger, especially in muscular men. In rapid effusions the skin is often obviously stretched. Œdema of the skin on the affected side is occasionally present, and, though not decisive of pus, is less common in serous effusions. It is confined to the affected side, but sometimes extends beyond the chest-wall. A great thickness of it may be attained very rapidly, especially with the more foul sero-purulent exudations. The state of the veins of the neck and of those upon the chest will be noted. Much enlargement of these would suggest intrathoracic tumour with or without fluid; as would inequality of the pupils, or other evidence of solid pressure within. Cyanosis will appear if the yielding right auricle is under much external pressure. Clubbing of the fingers (on both hands) may often be seen in old cases of pleuritic effusion not necessarily phthisical; and the feature

recedes if the patient advances towards recovery (p. 548). The presence or absence of a heart-beat and its position, if visible, must be noted. If fluid be in the left chest, a diffused pulsation in a tumid epigastrium often replaces the proper apex-beat, or the heart-beat may be felt (or heard) towards the right breast; if in the right chest, this beat may be detected towards or upon the left axillary line. The mediastinum is more readily displaced to the right than to the left side. In some cases of limited but complete dullness in the anterior and inferior region of the left chest, when it may be difficult to decide between fluid and pleuro-diaphragmatic adhesions, M. Jaccoud says the distinction may be made in some cases of adhesion by observing traction upon the lower ribs and spaces on forced breathing—the spaces being retracted on inspiration, and the ribs drawn towards the median line. In some rare cases of empyema the whole of the affected side so pulsates as to simulate a large aneurysm, a phenomenon which has not yet received a satisfactory explanation (see Diagnosis, p. 1277). Finally, in large effusions there is often some prominence in the hypocondrium of the same side; the nipple shifts farther from the sternum, and the shoulder-blade is thrust somewhat out and away from the spine. All these displacements and changes of shape are brought about more readily in young subjects; and in women more readily than in men. Yet in children, again, on account of the elasticity of the parts, we find proportionately less visceral displacement. The diaphragm in the female is more readily depressed than in the male, and the right side of it more readily than the left. In chronic cases absorptive and atrophic changes tend to bring about a shrinkage of the affected side; the thoracic and intercostal muscles waste; and the ribs touch and lap over with corresponding flexure of the spine, and great elevation of the heart or liver. Such a deformity, happily rare, may, indeed, if the lung be obliterated, be permanent.

Palpation will help us to estimate differential expansions; to find the heart's beat; to ascertain whether liver or spleen be displaced, and so forth. By the hand we may sometimes detect the creaking of friction, of which, indeed, the patient himself is sometimes aware; and we may verify the imperfect expansion of the side or abdomen, the levelling of the intercostal spaces up to the ribs, and possibly fluctuation in the former. The most distinctive sign to the hand, however, is the loss of the vocal thrill, which is arrested by fluid effusion. This is normally more distinct on the right side and over the lower two-thirds of the chest. Here effusions usually first accumulate, and loss of this thrill is almost pathognomonic of them; for it occurs besides only with those intrathoracic growths which by their size or position close the bronchial tubes, and in certain rare and peculiar cases of pneumonia with blocking of the tubes. Unfortunately, at a time of need the voice may fail in a woman, a child, or a very fat person, to awaken a thrill even in the normal parts. Sometimes the limits of the thrill may give a gauge of the height of the effusion, or may locate an adhesion. Above the limits of the effusion or near the spine the thrill is often more distinct than it is over the corresponding part of the sound side; and it is said to be present at times, or even increased, when, after re-absorption or withdrawal, but a very thin layer of fluid lies between the lung and the chest-wall. In such a case some

dulness would persist. Return of the fremitus is an early sign of recovery.

Percussion reveals a higher or duller note over the whole extent of the fluid; but it cannot tell us the amount of fluid present, as the level of this depends on the state of the lung and of intrathoracic tensions and displacements. Moreover, during absorption, dulness depending upon thick false-membranes cannot be easily distinguished from that due to fluid. Such membranes may diminish vocal fremitus also. When fluid is present in quantity, say in a layer of an inch in thickness, the note struck is dull, as if struck upon the thigh; and the stricken finger receives a peculiar sense of loss of resilience in the chest-wall. Extreme degrees of consolidation, however, may rival fluid in these characters. If the pleura seem full of fluid, but the lung be not much compressed, direct percussion by the finger-tips will give a very dull note and a sense of resistance, while a stronger mediate percussion will bring out a note of somewhat lower pitch. A very small effusion lying below the lung may be detected by comparative percussion on forced inspiration; as on the affected side, fluid will rise in the cleft between the pleural surfaces, which on the normal side will be filled by expanding lung. In an early stage of effusion the level of the dulness may perhaps vary a little with the position of the patient, if its quantity be moderate, and it be unconfined by adhesions. Gravitation, however, helps us less in inflammatory effusions than in hydrothorax. In pleurisy, indeed, the fluid may be sacculated, or even suspended by adhesions above the base-line of the cavity. When free and moderate in amount, the level of the fluid usually sinks a little, in a parabolic curve, from back to front. This curve, formerly attributed to the direction of the shrinking of the lung, is now known to be due to gravity together with the viscous quality of an inflammatory exudation. It is not seen in patients who have not taken to bed, nor in hydrothorax. Inflammatory effusions tend in a few days to 'set' in the position determined at first by gravitation, as the patient was then more upright or more recumbent. In acute pleurisy the fluid does not often rise above the third rib in front; but in quiet effusive pleurisy the whole moiety of the chest may become very dull upwards and across to the opposite parasternal line; and there may be dulness as well as bulging in the supraclavicular space. When the chest contains a good deal of fluid, but is not full, percussion over certain areas may actually give a lower note, or possibly a higher 'cracked pot sound,' but in either case with a tympanitic clang. These tympanitic areas are of three kinds—(1) where a thin layer of fluid lies over expanded lung, as, for instance, at an intermediate zone between clear lung and copious effusion; (2) where distended air-cells compensate cells closed in another part; (3), where, the chest being full of fluid and the lung collapsed, percussion in the neighbourhood of the trachea and large bronchi causes vibration therein. Tympany, when present, is ordinarily under the clavicle (Skodaic), but it may be distinct at the upper level of the effusion behind, say below the spine of the scapula. If the tympany be due to the third cause, it may have something of the cracked-pot quality. In some cases the tympany is decreased on inspiration and increased on expiration. The detection of tympany under the clavicle may mislead the unwary into a belief that the healthy side is morbidly dull; on

the other hand it is an invaluable help to the physician who takes it as a hint to look for mischief below: in rare cases this may be extensive consolidation without fluid. Dulness due to an elevated liver may be distinguished by the removal of its boundaries on inspiration, and by its anterior rather than posterior disposition. In mere hydrothorax the lung generally rises more readily, and the diaphragm and other parts can usually be made to move in respiration. On the left side the tympany of the gastric area becomes obliterated, unless the stomach be retained by adhesions, which has occasionally given rise to doubts.

Auscultation, before any dulness appears, usually reveals the respiration at the part to be defective in quantity, rhythm, or quality; and a friction-sound may be audible. Defective inspiration at the outset is due to checking of that act; afterwards it is due to the false-membranes and effusion which favour retraction of the lung, hinder conduction of sound, and ultimately silence it. A friction-sound, if generated, may be fugitive and escape the observer, or the embarrassed chest-movements may fail to give it distinctness; on the other hand it may be even palpable. If the heart modify its rhythm a pericardial rub may be simulated, but friction will vary with respiration. Usually it appears at the outset, and disappears as effusion separates the surfaces; it may reappear as the fluid is absorbed. Frequently it accompanies one only of the respiratory movements—the inspiration or the expiration. Friction is most frequent in the subaxillary area, and is often compared to the creaking of new leather or of parchment. The 'friction of onset' may last but a few hours, and except in dry pleurisy, or that of some cachexies or of septicæmia, is rarely abiding; returning friction is often coarser than the initial, and may continue for a longer time, even for weeks. It is not uncommon to find a friction-sound abiding so long as the patient can be kept under observation; these permanent rubs often seem to be without much practical importance. Diminished breathing and friction, if effusion gather, are followed by intermediate phenomena due to thin layers of fluid. These are bronchial breathing, bronchophony, and ægophony. Ægophony is nearly always heard near the root of the lung under the scapula; it has the character of a tremulous bleat, and when once heard is not easily forgotten. It may be reinforced by bronchophony, especially if there be solid lung below. Its presence is pathognomonic of fluid;¹ but it is so often absent that it is of little practical value. As fluid increases, these phenomena sound more distant, or give place to silence; and as fluid gathers first at the bottom we often find silence at the base; bronchial resonance, amounting, perhaps, to ægophony, at mid-lung; and either weak or compensatory breathing at the apex. We may also meet with curious inverse changes in the physical signs, notwithstanding an increase of fluid, if at first this be spread over a partially expanded lung, and afterwards accumulate below it as the lung retracts, or as intrathoracic pressure tells on the mediastinum. Thus dulness may actually recede with an increase of fluid, or on the other hand may rise upwards as with a diminution of fluid the re-inflated lung descends. For these and

¹ Some modifications of pectoriloquy have been described by Baccelli and other writers as means of distinguishing between pus and serum in the pleura, but they cannot be relied upon.

other reasons it is very difficult to gauge the ebb of intrathoracic effusions, or accurately to ascertain their behaviour after tapping. The cyrtometer and the tape are perhaps the most useful aids at such stages. If heart or liver had been displaced their return would be significant. The affected side usually retracts more or less as the fluid is removed. In some chronic cases where the lung does not re-expand well, and false membranes contract, the falling in may be considerable; and, as the muscles of the affected side are apt to atrophy, may appear to be even more than it is (*see* PNEUMONIA, CHRONIC). In children, bronchial breathing and bronchophony often, but not always, persist throughout. Where the lung is unbound, gauging is of course the more easy. When the chest is quite full of fluid, there may be no response to ear or hand; but even in such cases a faint but distinct respiratory *souffle* is not infrequently audible almost down to the base; and may deter the inexperienced physician from puncture. Breathing, more or less tubular, and some resonance on percussion are generally to be heard over the root of the lung in the vertebro-scapular space. The gradual formation of a pulmonary fistula may in some cases be revealed some days or hours before evacuation, by the presence of crepitations in the upper part of the affected side. As air re-enters the lung, respiration is at first weak, and accompanied by crepitations which are probably due to degrees of œdema; sometimes this œdema is severe and persistent, and abundant crepitations, with watery expectoration, last for many days. This is not uncommon after paracentesis. Respiration then improves gradually, and reinforces itself as the lung expands and clears. The pneumonia of children being often lobular, the discovery in them of bronchial breathing and bronchophony is suggestive of fluid, though lobar consolidation is of course not uncommon in them. In the other lung there is usually a slight general lowering of the percussion-note and a compensatory increase of breath-sound; if the effusion be large enough to compress the opposite lung, the percussion-note may be much lowered. About the lower half of this overworked lung some crepitations may be heard, especially if the right auricle be compressed. Finally, the stethoscope will aid in ascertaining the position of the heart. Skiagraphy is of use in doubtful cases. Serous effusions give a darker shadow than the normal lung, and purulent effusions are darker still. The position of the heart and diaphragm also may be perceived; so that in subphrenic disease (*see* STOMACH, PERFORATION OF) the X-rays may prove very helpful. The lung also may be perceived lying upward, inward and backward, or otherwise displaced, as in cases of adhesion or of fibrosis.

DIAGNOSIS.—Pleurisy in the earliest stage may be beyond diagnosis; or a pain may be felt, which, setting aside other causes, may be due to pleurisy or to pleurodynia. The pain is often referred to the loin or abdomen, thus leading to suspicion of disorder elsewhere. Prolonged anæmia and leucorrhœa would suggest pleurodynia. A comparison of local temperature in the two sides seems untrustworthy, but the presence of fever would make us strongly suspicious of pleurisy. It must not be supposed that diagnosis in this early stage is unimportant. Few errors are more common than the attribution of pleuritic pains to pleurodynia; the pain disappears, effusion slowly accumulates, and

mischief and peril, perhaps hardly remediable, may be the consequences. The careful observer will listen repeatedly to the chest for a friction-sound, which is conclusive. Fever might be present with pleurodynia, and an immediate diagnosis impossible, unless something characteristic in the stitch and start on deep inspiration betray a pleurisy. Neuralgic and inflammatory diseases of the walls of the chest are not likely to give rise to much misunderstanding. It is said that a pericardial may be mistaken for a pleuritic friction-sound, but the distinction can rarely be difficult; a pleuritic patch overlying the pericardium may chafe with a cardiac rhythm, but the sound would be modified by the respiration. A difficulty is more likely to arise in distinguishing between a pericardial and a circumscribed pleuritic effusion; still, with the inter-current respiratory rhythm, this can hardly be insuperable. In rheumatic fever, scarlatina, and streptococcal diseases pericardial may accompany or ensue upon pleuritic effusion, and when the latter is on the left side, and is abundant, the former may be confused with it, especially as in such cases the pericardial effusion is apt to lie in the back part of the sac, and thus elude discovery. The practical lesson is to remember the likelihood of pericardial effusion, and its frequent latency.

In the later stages of pleurisy, when effusion is abundant, its diagnosis may at times be difficult. Under ordinary circumstances complete and extensive dulness, with loss of sense of elasticity in the chest-wall, of respiratory sound, and of vocal thrill, makes diagnosis easy; or if there be resonance below the clavicle, its high pitch is characteristic of fluid below. But there may be no such resonance, and the voice may fail, or fail to set up thoracic thrill. Moreover, vocal thrill and respiratory murmurs may vanish likewise in intrathoracic tumours. Thus the diagnosis between exudations, pulmonary consolidations, intrathoracic growths, subphrenic mischief, and combination of pleuritic fluid with any of them, is sometimes difficult. If empyema coincides with acute pneumonia and overlies it, a differential diagnosis may be unattainable; but absolute dulness, cessation of vocal fremitus, distance of respiratory phenomena, and a recrudescence of fever after a crisis would suggest exploratory puncture. In the writer's experience inordinate severity of the pain in the side is characteristic of gravity in the nature of the pleurisy. The heart may be dragged over by the retraction of the opposite lung. Leucocytosis, absent in simple serous effusion, would suggest empyema, pneumonia, or tuberculosis. In small effusion the limits of posterior dulness may be raised by a few forcible inspirations, probably due to a re-expansion of collapsed lung; or if there be no effusion they may be reduced as the inflated lower border of the lung reoccupies the cleft behind an elevated diaphragm. Two fingers' breadth of dulness at the base signifies about 15 oz. of effusion. If the voice be ægophonic we decide upon fluid, but if bronchophonic we may distinguish the 'sniffing and metallic' bronchophony of consolidation from the weaker and more diffused bronchial quality in pleuritic effusion. The same may be said of the respiratory sounds. If perchance the dulness and breath-sounds should vary with the position of the patient, fluid is clearly manifest. Circumscribed effusions, such as

encysted empyema, if they do not displace the heart, are at times physically indistinguishable from a like extent of chronic consolidation, or of abscess in the lung. Such effusions, though usually basic, are by no means always so. Retained by adhesions and sometimes multilocular, they may occupy the upper and anterior region, any part of the middle region, or strips or irregular districts in any direction; or, again, they may be interlobar, and in this position perhaps to be recognised by the obliqueness of the strip of dulness. Interlobar effusion is usually purulent, and often is revealed only by breaking upwards, when it behaves as a pulmonary abscess. It may be said, in general terms, that a permanent dull area remaining after an acute pleurisy or pleuro-pneumonia is most probably due to an encysted empyema, but not always. In such cases fever, if it recur after a pneumonic crisis, is a tell-tale symptom, but it may be entirely absent, and, unless clubbed fingers or radiography help us, there may be little to decide the nature of the disease. Obsolescence may result; still such a collection is very likely to work mischief sooner or later. The difficulties of distinguishing the more bulky effusions from pulmonary consolidations are not often great. In the former the intercostal spaces may be bulged, and the moiety of the chest enlarged; but these signs occur in some rare cases of 'caseous pneumonia.' On the other hand, consolidation very rarely reduces the lung to silence, though this may be the case; if so, the bulk of the half-chest would in all probability be lessened, but so, on the other hand, may it be in a chronic effusion. The upper line of dulness in effusion is a very inconstant curve, determined by the posture of the patient during the time of its initiation. The fact is, many chronic cases can be diagnosed only by the needle; and it should be noted that, even with the needle, many punctures may be needed before deciding against fluid. Practically speaking, however, as Wilks has said, 'chronic basal pneumonias,' unless of subphrenic origin, are almost always pleuritic effusions. Pulmonary abscess too is rare, and it may be separated from the visceral pleura by a layer of pervious lung. If it lie near that surface it may be indistinguishable from an empyema; and this is the more embarrassing as adhesion is very often wanting, even in abscesses of some standing, when exploration by the needle is not without danger. It is difficult to do more than to urge the physician before plunging in the needle to consider the importance of a full review of the history of doubtful cases. Between intrathoracic tumours and large pleuritic effusions a difficulty is found only in those cases in which the tumour is confined to one moiety of the chest; this, however, is not very uncommon, especially in aneurysm. If fluid effusion accompany tumour, there may be subtympantic resonance under the clavicle. In favour of fluid alone are the absence of enlarged veins; the equality of hydrostatic displacement of organs, and the absence of signs of local pressure, of retarded arterial wave, of inequality of pupils, of peculiar sputum, and of enlarged glands.

A curious pulsation, of uncertain explanation, is sometimes seen in left-sided empyema, or any effusion, if tense enough, and very rarely in pneumonia alone (Graves). In the case of effusion, indeed, the lung must be indurated and must be tied down to the structures about the heart. This pulsation must not be mistaken for an aneurysmal throb. If

fluctuation be felt in the intercostal spaces, the disease, in part at any rate, is a fluid effusion. Sometimes a gastric, hepatic, biliary, renal, or other subphrenic abscess, making its way by a sinus, occupies some part of the pleural cavity, or excavates an adherent lung. Such an abscess usually extends rapidly, but it may encyst itself, and remain latent or quiescent for months; or it may excite an effusive pleurisy in the remainder of the cavity, so that two effusions co-exist in one pleura. Thus, serum may be withdrawn from one part of a pleural cavity, while a collection of pus remains encysted in another—a collection, even when suspected, perhaps very difficult of discovery. From it of course pulmonary fistula may take its origin, and pus from the same central source, whatever the origin—for instance, hepatic, perihepatic, or perigastric abscess, renal stone, appendicitis, caries of bone, and so forth—may in part issue from the urethra or rectum, and in part issue from the mouth. Pleurisy, even without effusion, at the bases of both cavities is very suggestive of a sub-diaphragmatic origin, and, still worse, of the possible presence of pus in the mediastinum; though tubercular peritonitis is often associated with tubercular pleurisy which may be bilateral. When such abscesses contain air, but not by way of the lung, they may have originated in some perforative disease of stomach or bowel; in these cases, however, there will be little evidence of retracted heart or of increased intrathoracic tension, and the affected area will rarely approach the apex. Dulness from disease below the diaphragm, but encroaching on the thoracic space, may be displaced downwards by a deep inspiration. Radiography is proving itself a valuable aid in exhibiting such displacements, as of mediastinum, heart and diaphragm. Radioscopy in some cases is remarkably efficient; as when on the screen the movements of the diaphragm are rendered visible, and the varying level of fluid, so that in succussion the splashing may be seen. It is stated that in puncture combined with the use of a manometer, when the canula is in a cavity beneath the diaphragm, inspiration is attended with an increase and expiration with a decrease of pressure, being the reverse of that which occurs when the canula lies in the pleura. In peripleuritic abscess tension is of course low, there is no pressure on neighbouring organs, percussion-dulness is less profound, free expansion of the lung may be detected, and axillary glands may be enlarged. It is said (Bartels) that pus from interstitial abscesses is of higher specific gravity (1040) than from large cavities (1028-1030). Pleural effusions arising by direct absorption from puerperal and like forms of peritonitis are usually themselves also septic.

The diagnosis between serous, sero-purulent, and purulent effusions is usually decided by the needle. Even in the case of recent limited basal effusions the physician must suspect empyema. Signs, such as oedema of the skin, said to be indicative of pus, are by no means trustworthy, and the chest-wall may be retracted over pus as over serum. By radiography no doubt the transition of serous into purulent effusion is perceptible, but in ordinary practice this means of diagnosis is rarely available or necessary. Collections of pus or serum in peculiar situations may then be fairly easy to discover, or difficult, or impossible. We shall remember that such collections contained or suspended by adhesions may

occur, and moreover may be multilocular. In the most important of these—the effusion between the lobes of the lung, which is usually purulent—radiography may be very helpful. If the case be followed from the beginning the changes may be noted along the lines of the fissure. Often, however, it is first revealed by perforation into a bronchial tube. If the liability to collection here, or between lung and diaphragm, which is far from uncommon, be present to the mind of the physician, the symptoms and course of the case will usually indicate to him the duty of careful and even repeated exploration in these areas.

A large pulmonary cavity might be taken for encysted empyema with fistulous opening into a bronchus; and here again, as a pulmonary fistula rarely gives rise to tubular breathing, unless the opening be very large or communicate with a secondary cavity, diagnosis by direct signs alone might be impossible. The history of the case and the state of the other lung would be important factors in decision. In another class of cases the distinction between chronic phthisis and pleurisy may be difficult—in those, that is, in which there is some old dulness and retraction of a part of the side, dropped shoulder, atrophied pectoral muscles, weak respiration, indefinite crepitations, and more or less fever. Absence of bacilli and lung-tissue in the expectoration, and the health of the other side, help to exclude all but that fibroid phthisis which is usually a result of chronic tubercular pleurisy. Tubercle-bacilli are rarely to be found in the effusion of such pleurisies and do not survive long in pus; but a positive result may be obtained on the guinea-pig if 20 cc. be injected (*vide* paragraph on *Ætiology*). In the pleurisy of typhoid fever, the effusion, of whatever kind, has a high agglutinative power. In children, enlargement of the spleen, with extension upwards and backwards, has occasionally simulated effusion at the base of the left lung. Hepatic hydatid may rise up to the third rib; it has usually a convex upper border, but it may be distinguishable only by the properties of the fluid drawn off, which is non-albuminous and contains hooklets. The distress and orthopnea of very painful pleurisies—of diaphragmatic pleurisy more especially—may simulate cardiac thrombosis. The state of the pulse alone usually suffices to abate the fears of the physician. A hæmorrhage into the pleura can be distinguished from a serous or purulent effusion only by a careful survey of all the history and symptoms; the direct physical signs help us but little.

PROGNOSIS.—The prognosis of pleurisy, even tubercular, apart from pulmonary tuberculosis or malignant disease, is generally favourable; in tubercular pleuritis it is usually favourable as regards the current illness. In children the prognosis is especially good, although in them the effusion is often purulent (usually pneumococcic). Chronic pulmonary fibrosis is happily rare, and in the particular case the chance of such an event almost vanishes. When the effusion is large it is the less favourable the greater the quantity, the slower the absorption, and the more obstinate the recurrence, especially if the patient makes no way. Coagulation in the serous exudate on standing is favourable, a heavy deposit of leucocytes is less favourable. Irregular or remittent fever and loss of flesh are of grave significance. Signs of hyperæmia and œdema in the working lung must be anxiously watched, especially if an empty radial artery, scanty

urine, and other evidences of high venous pressure be added. When the chest is full, prognosis, apart from operation, is bad. In severe and rapid cases the other lung may become œdematous and congested, bloody and frothy sputa appear, carbonic-acid poisoning become evident in the blue lips and lethargic brain, the pulse slip away, the heart fail, and the extremities grow chill; or, again, death may be sudden, as if due to syncope. Sudden death in pleurisy with effusion has been attributed to torsion of the great vessels, due to the dislocation of the heart; but such torsion does not occur, and the accident may happen in large effusion on either side of the chest, or, indeed, with effusion of moderate degree, and may be due to thrombosis of the pulmonary artery, to pericardial effusion, or to compression of the right auricle. Operation raises the hope of recovery greatly—so much so as to put the chances largely in favour of rapid recovery in ordinary cases. The earlier the relief, the less the damage to the parts and the better the hope of rapid amendment. In bad cases prognosis will be the less favourable the more potent the adverse conditions; and in secondary pleurisies the prognosis may depend upon these other conditions. In old people operation is still useful; the conditions in them unfavourable to operation are still more unfavourable to absorption; but especial care must be taken to draw off the fluid very slowly, and to watch the circulation. In empyema prognosis is graver; unless operation be performed death is probable, either by syncope before the matter escapes, or by exhaustion, chronic septicæmia, or secondary abscesses, during a long period of incomplete drainage of the chest. If operation be submitted to, the prognosis is favourable, save in the worst cases; the earlier the operation is performed the better. Cases of the thick, greenish pus of the pneumococcus, seen more often in young children than in adults, do better than the seropurulent of streptococci. But these characters are not conclusive, and must be checked by cultivation. Sometimes in bad cases, such as those of a septic or gangrenous kind, death is preceded by much dyspnoea, due to cessation of all abdominal breathing. A very small gangrenous patch in lung or pleura will betray itself by its unmistakable odour. Although primary tubercular pleurisy with serous effusion is hopeful as regards immediate prospects, tubercular empyema is far less so; indeed, its nature is often to be inferred mainly from its vicious course. Effusions secondary to pulmonary tuberculosis, when they are serous, as is ordinarily the case, should be left alone as long as possible. Among the deferred dangers are amyloid disease—not a common event, but possible in cases of necrosed rib or other bone or of long and exhausting drain, and phthisis or more general tuberculosis, happily rare, prevented, it may be, by the density of the false-membranes. The presence of albumen in the urine does not preclude recovery nor forbid prompt operation. The precise bearing of age and sex upon prognosis cannot as yet be decided. Experience indicates that it is more hopeful in cases under ten years of age and above twenty years. Bowditch says that full pregnancy is no bar to thoracocentesis.

As regards duration, an ordinary case of inflammatory pleurisy will last from ten days to a month, according to the degree of effusion and the rate of re-absorption. Chronic cases with large effusions

may last any length of time, rarely less than three months. If tapped, the fluid may not return, or may not return after a second tapping; in such a case recovery will be more rapid. Empyema, opened under the most favourable conditions, is often months and sometimes years before final closure; antiseptic operations and dressings have much shortened the mean duration. If left to itself, an empyema usually opens through the lung or externally. In the latter case the issue is most commonly about the fifth interspace anteriorly, but may appear elsewhere. Drainage in such cases is very incomplete, and although some relief is attained, the patient nevertheless drags on, it may be for years, with a permanent fistulous discharge. Operation in such cases is discussed further on. Of double empyema many cases have ended in recovery, especially in children.

It must not be forgotten, however, that simple pleuritis, so often themselves tubercular, may be the forerunners of phthisis, even years afterwards. The occurrence of a pleurisy in a young person is always then an anxious matter. The experienced physician will call to mind many cases in which a pleurisy, to all appearance wholly recovered from at the time, was followed even before many months had passed by definite signs of phthisis. Prognosis, therefore, must concern itself with the ultimate as well as with the immediate issue, and with the appropriate warnings. In the course of pulmonary phthisis a decided attack of pleurisy means or makes mischief, even if quickly got under.

Hæmorrhagic effusions, if kept aseptic, often do well; their gravity depends upon the cause. Of secondary purulent foci which may take rise in empyema, suppurative meningitis and abscess of the brain are the most calamitous, and, unfortunately, not the least common. Nystagmus, or other muscular spasm, may put us on our guard; and the fluid of lumbar puncture may be examined for microbes (see p. 903).

TREATMENT.—(1) *Medicinal.*—Dry pleurisy requires little treatment. In some cases, as in chronic phthisis, it may cause distress, and, if so, may be relieved by spongiopiline and laudanum, or other such soothing measures. In the cases in which a troublesome cough is caused by a patch of chronic dry pleurisy, the cough and pleurisy alike may be relieved by the brief application of blisters. In acute pleurisy, on the other hand, much depends upon treatment at the outset; in few maladies is early attention better rewarded. Our aim in the beginning is to diminish pain, inflammation, fever, and the tendency to excessive exudation. With or without treatment, the pain usually passes off in forty-eight hours, or thereabouts; nevertheless it is very acute while it lasts. In sharp cases, occurring in healthy persons, we may put on six to twelve leeches according to the age, sex, or condition of the patient, and these may bleed freely into a large poultice. This measure, if adopted at the very outset, diminishes the pain, the fever, the exudation, and the duration of the case. When the bleeding has ceased, the chest should be firmly bandaged, and so soon as the state of the leech-bites will allow of it the affected side should be as firmly strapped. This, by giving rest to the part, will favour resolution and resorption, and some patients, though not all, find much comfort from it. Respiration, on the other hand, favours effusion, as does exercise in inflammation of a joint. If called to a

case after the first brunt is over—say after a lapse of forty hours—it is better to omit the leeching, in order that the strapping may be applied at once. It must be applied on the method laid down by F. T. Roberts. Dr. Roberts applies the strapping in all cases from the outset; but the writer's experience is in favour of early leeching in suitable cases. Some physicians recommend that an attempt be made to subdue the local inflammation by the application of ice-bags, but the results of this method do not seem very satisfactory. In addition to local measures, such medicines as the following are required: A combination of compound ipecacuanha powder and antimonial powder (āā gr. iiss) may be given every six or eight hours, for two or three days. When pain is severe, the subcutaneous use of morphine is to be recommended, in doses of one-eighth to one-fourth of a grain. In addition to the above powder, either full doses of solution of acetate of ammonium (ʒij-ʒiv for an adult), or ten grains of salicylate of sodium, every four hours, certainly relieve the symptoms if they do not change the course of the acuter pleuritis. A saline effervescent mixture may be freely used also as a drink, whereby activity of the skin and kidneys is promoted. In the earlier stages free purgation should be avoided, but it is well to call gently upon the alvine excretion by the use of mercurials and salines. All solids must be withdrawn from the dietary, and stimulants, as a rule, forbidden. The saline effervescent or a cream-of-tartar drink is to be continued after the powders are withdrawn, so as to keep up free excretion; for the same purpose, and also to lessen chest-movements, the patient must be kept closely to bed. For some days after the subsidence of the fever the appetite must be held in check, and it is desirable at this stage to lessen the amount of fluid in the dietary. Thus it is to be hoped that, as the patient's general condition improves, the effusion in the chest may likewise fall. If this be not the case blisters seem certainly efficacious; not pushed to full vesication, but repeated frequently. Iodine-paint, in the writer's opinion, is useless. At the same time, or soon after, a pill may be administered twice or thrice daily, containing a grain each of digitalis (fresh leaf) and blue pill. The digitalis, by keeping up the arterial blood-pressure which tends to fail, favours excretion; and mercury is one of the best of diuretics. The use of blisters and mercury must be avoided if the kidneys be not sound, and mercury should be avoided if phthisis be suspected. When a brief and gentle eliminative course of this kind is ended, restorative treatment, with such drugs as iron and quinine, should be substituted. Delicate and anæmic subjects may need iron and bitters, cod-liver oil, and liberal diet from a very early stage, and such cases are not uncommon. But such measures are not to be used in the acuter stages, a precaution too often forgotten; even in phthisis a sharp intercurrent pleurisy must be treated at first by salines, and possibly even a leech or two.

These measures will generally help to reduce not only acute effusions of moderate extent, but also of a more obstinate kind. If, however, the case resist the means prescribed, the effusion will probably increase, and operative interference may be urgent, as is so commonly the case in latent pleurisy. As a general rule, if a primary serous effusion rises much above the angle of the scapula, and abides, in this quantity or more, for two or three weeks in spite of

adequate treatment, it must be drawn off, whether the patient be embarrassed by it or not.¹ An effusion, however small, known to be purulent, must be removed at once. The presence of fever is no obstacle to operation. In cases in which treatment by medicines has not been fairly tried, when the patient is in comparative ease, the effusion is not above the spine of the scapula behind nor above the mamma in front, is not rising, and the neighbouring organs are not much displaced, operation may give place to medicinal treatment for two or three weeks longer. The writer, however, would advise the withdrawal even of a pint of fluid which had lain in the cavity for a month, unless there is pulmonary tuberculosis, as its continued presence promotes retraction of the lung, and tends to destroy the absorbent power of the pleura and of its granulations. Sometimes at a later date, when convalescence should be established, a still smaller quantity of fluid may be detected, and the patient remains poorly and out of condition. An inch or two of fulness persists at the base of the lung, and on puncture such remnant may prove to be pus, which would, of course, be dealt with thoroughly; yet even if serum only be found the withdrawal of it for some obscure reason seems to set the patient free to get well, if there be no other complication. If there be effusion in both pleural cavities, the mounts must be considered, of course, as one quantity. Before speaking at length of operation, however, it is well to say that two other methods remain—the so-called ‘thirst-cure’ and the jaborandi-cure. The first method consists in the withdrawal of fluid from the diet, which should consist of lean cold meat, stale bread, and the like. All fluids are forbidden, except half a pint on the third day, and a pint on the seventh and eighth days. The effusion is said to decrease daily under this method, but it is more painful than tapping, and could not be borne by all patients without injury. The second plan, to which excellent results are imputed, consists in the promotion of profuse sweating, by means of jaborandi. The drug is administered as a liquid extract, ʒj being given every three hours; or one-eighth to one-third of a grain of nitrate of pilocarpine is injected subcutaneously, and repeated as the results may indicate. The writer has not learnt to rely on the former method, and the latter he is indisposed to try. It is well, however, to control the amount of fluid taken. If medicinal and dietetic means fail to remove a moderate effusion, if the fluid be rising fast, or if it occupy the whole or, persistently, a great part of the pleural cavity, the cavity must be tapped. There should be no hesitation in tapping instantly any chest, even in cases of phthisis, which is dull up to the clavicle, or presents but a small tympanic space under the clavicle.

(2) *Operative*.—To ascertain whether the fluid contents of the chest be serous, sero-purulent, or purulent, an exploring syringe may be passed through the wall of the chest, and a specimen of the fluid drawn off. In this way information is obtained as

to the nature of the fluid, its accessibility, and its bacterial contents. Should no fluid be obtained, the puncture can be repeated at another spot more readily, and with less sense of failure, than a greater operation. The site of operation must be chosen with care; happily, there is plenty of margin for error. In encysted empyema with thickened walls we repeat that four or five punctures may be needed before pus be reached, and a negative result must not be accepted without examining under the microscope any drop or fragment within or upon the needle. In cases of multilocular effusion the emptying of one loculus only is of course an incomplete measure. Such cases can be dealt with only by repeated puncture.

The chest, as a rule, is to be tapped in the sub-axillary area, where there is little danger to other organs. Reasons to the contrary may present themselves in the case of adhesions tying the lung or diaphragm to the side or back of the cavity, of displacement of the heart, or of deformity. An oedematous area must be avoided, as access of pus may convert it into a large cellular abscess. The pointing of an empyema forward is no indication for an anterior opening, as this pointing will recede when a lower opening has been made; nor is the distant sound of respiration over the back of the affected side a reason for declining to operate posteriorly. Let any bulging of intercostal spaces be looked for, as at such a spot false-membranes are probably scanty; and let it be ascertained that there is room enough between the ribs for the insertion of a finger into the cavity; if not, a rib or two must be resected. The writer used to prefer the eighth space in a line with the angle of the scapula; but safe as is this position, and good for bottom drainage, elevation of the diaphragm often defeats the latter purpose and interferes with the tube. The anterior axillary line is too forward for safety and for drainage; the posterior line, or perhaps a little behind it, is usually the best place. Except, perhaps, in a very stout person a little difference in the thickness of the chest-wall is unimportant. If it should appear, however, that the fluid is so limited or encysted that it does not gravitate to the bottom of the cavity, or that it has a more anterior seat, a tentative puncture must be made at the dullest spot, regard being had, of course, to the position of neighbouring organs. Some years ago a ‘dry tap’ was a great disappointment to the patient’s friends, and an annoying rebuff for the physician. Now we are better aware that in obscure cases of circumscribed effusion such explorations may fail again and again and yet be finally successful, or in any case be an indispensable means of obtaining information.

After disinfection both of skin and instrument, the needle of the syringe must be thrust quickly through the tissues into the cavity, the operator being careful to enter a little below the mid space, so as to avoid the periosteum of either rib, and the intercostal artery above. There is no objection to freezing the skin beforehand, but if the edge of the canula present no ridge upon the trocar the stab is not very painful. If the fluid drawn be clearly serous, it may be well to wait a day or two to see whether a small draught will set up absorption of the rest. Many such cases are on record. If the case, as is very common, be of a tubercular nature, the reabsorption, thus accelerated, may, as

¹ In the revision of this article these words are left as originally written. The writer is aware that of late recourse has been had earlier and more frequently to paracentesis; but his own experience leads him still to counsel delay so long as the patient is in no distress. Acute serous effusions advance to a moderate limit, and then slowly recede. If drawn off during the period of increase the puncture will not prevent reaccumulation, in which case it is a useless vexation.

is alleged in peritonitis, be useful by the introduction of some antidotal factor into the blood. Certainly many of the cases in which absorption is thus started, either in pleura or peritoneum, do unexpectedly well. As a rule, however, it will be needful to proceed to a further evacuation of the cavity. See PARACENTESIS; ASPIRATOR; and PLEURA, Surgery of.

It may be desirable to inject one-fifth of a grain of morphine beneath the skin after the operation, in order to relieve any irritation either by cough or otherwise, and to secure subsequent rest. In some favourable cases no second tapping is needed, and the heart tends to recover its position on the completion of the operation, moving three inches perhaps in the course of it. In two cases in which the writer noted reduplication of the second cardiac sound before tapping, the sign ceased at once on the emptying of the cavity. In other cases, even of serous effusion, the severity of the pleurisy may have so fettered the lung that the readjustment of the parts is much more gradual, and the space of the effusion is reoccupied but slowly by the unfolding lung, and the yielding of the chest-wall and mediastinum. In this respect there is not much difference between serous and purulent formations, save, of course, that neglected cases are more likely to have become purulent. A rapid return of the physical signs to the normal is a very good omen, and in cases promptly dealt with this is now a common experience. Moreover, if large adhesions take place they seem to stifle tubercle. In cases of slower recovery we get less help from physical signs, the conditions within the chest being in a more stable state of perversion. In pleuropneumonia the lung may not be able to expand after a paracentesis for the pleurisy, so that only some ten ounces or so may be obtainable by resiliency of the ribs. It is rather the rule than the exception for some dulness to remain below the scapula, and this alone is no indication for repeating the operation. In many cases, however, perhaps in the majority, often without any recurrence of fever, the cavity refills, and aspiration may have to be repeated more than once. It is proper, therefore, to warn the patient of this beforehand, lest he be discouraged.

If there be subsequent pain or elevation of temperature, these, under ordinary circumstances, will prove to be transient, but if the rise of temperature continue after the first day or two, the formation of pus is to be feared. This event is not infrequently attended by a re-awakening of pain. As a rule, the pus must be evacuated by free incision as soon as discovered. An anæsthetic must be used that the operation may be performed deliberately. Chloroform in these cases seems to put less strain upon the limited breathing-powers than ether. If for any reason, such as renal disease, general anæsthesia be undesirable, it may be obtained locally. See ANÆSTHESIA, LOCAL.

From the time of the operation the temperature should fall rapidly to the normal, especially if the patient can be in the open air, the value of which cannot be overrated in these cases; if it rise again, the rise will be almost surely due to occlusion of the opening.

In the exudations of phthisical or carcinomatous disease, operation may be justifiable by the temporary relief given to the sufferer; paracentesis must, however, be preferred to incision as long as

possible, as the incision may not heal. If after the removal of a collection of pus, and the establishment of really free drainage, the discharge become more offensive and the fever remain, the disease is probably a progressive tuberculosis, and the forecast unfavourable. It will be remembered, however, that the pus may not all be included in one cavity, or in cavities which communicate; if so, each separate cavity must be opened.

There is no substantial difference of method in operating upon a case in which a pulmonary or other ill-placed fistula has already formed. The performance of the operation in such cases, if the bronchial opening be free and not valvular, and especially if there be much adhesion and length of sinus, is not generally indicated; and its need must be estimated by the behaviour of each particular case, especially by the temperature and the freedom of expectoration. In these cases the open-air treatment may suffice. In rare cases it may be possible to drain a pyopericardium through the pleural opening. In double empyema a day or two should, if possible, be allowed to intervene between the two operations, especially in children; there is some risk of collapse or of pulmonary oedema in doing both operations together, unless the empyema be encysted on one or both sides, when operation adds little to the disturbance.

After each or any removal of fluid from the chest the re-expansion may be assisted by respiratory gymnastics, by graduated exercise, by the inhalation of compressed air, or by residence at high elevations. Massage and faradism may be useful. Finally, the importance of treating the patient from the time of operation in the fresh air, as in phthisis, must be emphasised. The writer has seen very unpromising cases answer surprisingly to this method, even where operation was inadvisable.

3. Pneumothorax.—Fr. *Pneumothorax*; Ger. *Luftbrust*.

Pneumothorax is the state in which the pleural cavity, normally non-existent as a space, contains air or other gas. If the air or gas be present together with pus, blood, or a watery fluid, we give to the resulting states the compound names, *Pyopneumothorax*, *Hæmatopneumothorax*, and *Hydropneumothorax* respectively. The gaseous content in these cases may precede the entry of the fluid or succeed it; or it may be generated in the cavity by specific bacteria.

ÆTIOLOGY.—Pneumothorax is a commoner event than would be supposed, were we to confine our attention to cases recorded under this name. It is often an incident in the course of other diseases, and of none more often than pulmonary tuberculosis. Pneumothorax sometimes, but rarely, seems to appear as a primary event, disappearing again without further complication; usually it results from wounds of the chest, purulent pleuritis, phthisis, ulceration (simple or carcinomatous) of the œsophagus, stomach, bowel, or gall-duets, and so forth, opening into the cavity. If air be admitted mechanically to the pleural cavity, decomposition of other contents may add to the volume of that which was admitted. Even in those few cases in which pneumothorax seems ‘idiopathic’—in which, that is, we find pneumothorax to be the eminent morbid state—we are bound nearly always to assume this state to be secondary, and due to some perforation the cause and place of which may

escape recognition. Yet in some rare cases a strain seems to have ruptured the lung. Three cases in the writer's experience, occurring during violent exertion in vigorous men, recovered permanently in a few days; but, though tubercular perforation rarely or never heals, it is difficult to suppose that in any such cases the lung was perfectly sound. Cases due to wounds of the chest find their place elsewhere.

In empyema pneumothorax is apt to follow perforation of the lung with ejection of the pus upwards; or, more rarely, perforation of the chest-wall by ulceration outwards. In these cases of *pyopneumothorax* we have to deal, of course, with an abundance of both pus and air in the pleura. Pneumothorax, as we have seen, is a common complication of phthisis pulmonalis. When it occurs in the later stages of the disease, it often escapes observation; in the earlier stages its symptoms are less likely to be overlooked. Its occurrence may be determined by such a strain as a fit of coughing. That pneumothorax is not a still more common result of ulcerative processes in the lung is due to the anticipation of a breach of surface by previous adhesive inflammation. In phthisis the perforation is often minute, and the quantity of matter escaping into the cavity small—so small as to be inadequate to produce the physical signs of fluid contents. For obvious reasons the bursting of a phthisical cavity into the pleura is very rare; perforation is due to the ulcerative action of a superficial deposit upon the visceral pleura; such being its nature it rarely heals, but it may be enclosed by consequent adhesions. In other cases the escape is more abundant, or a more abundant effusion comes from the pleura itself, as a consequence of the resulting irritation. We have then to deal with an obvious sero-pneumothorax or pyo-pneumothorax. In cases due to tubercular perforation the effusion is generally serous, and if into a circumscribed cavity the sac may close up by adhesion. Air thus entering the pleural cavity, unless it pass through septic channels, is purified from such elements by its filtration through the lung. The mode of the opening by which air escapes into the pleural cavity is of chief importance; it may be, and often is, *valvular*, so that its entry during inspiration may not be balanced by its exit; in this case air accumulates under pressure. If, as in empyema, the lung be already collapsed, this pressure is the less distressing; if the lung be wholly or in part open, the pressure adds to the degree of the sudden embarrassment due to rapid retraction of the lung, absorption of its air by its blood, and encroachment upon the surrounding parts, including the opposite lung. The valvular action does not usually depend upon the shape of the orifice, but upon the retraction on expiration of the lung around it. This kind of pneumothorax, unless circumscribed, is relatively frequent, and more mischievous, as the tension may reach a very high degree. If the air have free issue, the pressure within is not above that of the atmosphere, and the air is readily reabsorbed. In puncturing the chest-wall with a fine trocar, in cases of serous effusion, the lung is sometimes wounded, and air escapes into the pleura. The accident is an untoward one; air passing through a healthy lung sets up no putrefaction, and is itself quickly absorbed, but a large quantity suddenly admitted may add a good deal to the suffocative distress of the patient.

Perforation into the pleural cavity by ulceration,

simple or cancerous, either in the lung itself or in such neighbouring organs as the œsophagus, the stomach, the bowel or connected ducts, is not very rare; the entry of air, food, or other foreign matters into the pleura in such cases adds greatly to the distresses of the latter days of life.

The last cause which needs notice is the action of ærogenic microbes in the cavity. Of these rare cases the writer has seen very few. In the last of them, a slow pleurisy of the right base, the dullness of fluid rose nearly to the spine of the scapula, with Skoda resonance above. Two or three days later an area of resonance of subtymppanic character formed in the midst of the dull patch and extended during the following two days. On percussion a disc of resonance was surrounded by a dull ring of perhaps a third of the common radius. On operation gas bubbled out and about a quart of turbid serum flowed away, of a peculiar but not gangrenous odour. After resection of two ribs the diaphragm and parietes were examined with the finger. Excepting some strong adhesions the results were negative; the surfaces smooth, no sign of perforation, no fluctuation, no evidence of pulmonary gangrene. But the operation gave no relief, subcutaneous hæmorrhages appeared, and the patient sank with subnormal temperatures and rapidly failing heart. Unfortunately no specimen of the fluid was reserved for bacteriological examination, nor could a necropsy be obtained.

ANATOMICAL CHARACTERS.—A patient rarely dies of simple pneumothorax; or if death be mainly due to this, yet unless it occur within the first few days it is probable that some considerable inflammation will be found also. In the vast majority of cases, of course, the pneumothorax is secondary to some other disease, and any fluid or other matters found with the air in the chest may be due, not to the mere admission of air into the cavity, but to the admission of decomposing elements into it. As concerns air alone, we have only to say that in the cases in which air has reached the pleura by a valvular opening, the affected side of the chest may be visibly distended. In such a chest the pressure of the contained air will be positive, and on puncture may escape with a hissing noise; the out-rush may indeed be strong enough to blow out a candle. This air is usually deoxidised, and rich in carbonic acid; if there be decomposing matters in the cavity, it is likely also to contain sulphuretted hydrogen. Neighbouring parts, especially the heart, will be found more or less dislocated, directly as the degree of positive pressure and inversely as the amount of adhesion. Bilateral pneumothorax, unless the lungs be widely extended by adhesions, is, of course, incompatible with life; if on necropsy it be found double, we may be sure that, on one side at any rate, it came on at the moment of death, and in this cavity no effusion will be found. If the opening eludes observation, it may be discovered by filling the cavity with water and injecting air by the trachea.

SYMPTOMS.—The symptoms of pneumothorax are of course the more distinct the less the symptoms of the primary malady. In those rare cases in which pneumothorax comes on suddenly as the primary disease—that is, in which the mode of entrance of air into the pleural cavity is unknown—we find the chief symptoms to be dyspnoea and a sense of faintness; pain is a less uniform but often very severe symptom, and worst

when the entrance of air is followed by irritation and inflammation due to the fluid or solid matters which accompany the gaseous. Aseptic air alone does not set up much irritation. Fever, in like manner, depends not upon the entrance of air, but of the irritating matters which accompany it. Like the pain, it may be considerable; it may not be present at all; or, again, it may be lost in the fever of the primary malady, or betray itself but as a slight exacerbation of this fever. The dyspnoea, chiefly mechanical, in part reflex, is necessarily attended by increase of pulse-rate; the two events being but different aspects of the same machinery. The degree of these accelerations depends upon the rapidity of attack, the amount of previous accommodation in the chest, and the quality of fluid and solid concurring with the gaseous escape. That in full or extensive pneumothorax the symptoms are in-grossescent, and far more injurious, with the valvular mode of opening we have already pointed out. The escape of air with irritating matters suddenly into the open pleural cavity of a person suffering but little, if at all, from a tubercular ulceration, or of one surprised by an accident in the midst of health, may cause dyspnoea almost suffocative in degree; intense pain, anxiety, lividity, clamminess, chilly breath, faintness, great acceleration of the pulse, and distension of veins in the neck. On the other hand, in pneumothorax occurring towards the end of phthisis, when a pulmonary ulcer breaks through a pleura widely adherent about a lung already half destroyed, the attack of chest-pain which follows a bad fit of coughing may be put down, like the dyspnoea and the pulse-rate, to the fatigues and distress of a restless night. The patient's general condition may not be much altered in such cases. Cough and expectoration in simple pneumothorax are slight; but if pneumothorax be established on the bursting of an empyema into a bronchus, expectoration uniformly purulent will be the most prominent of the symptoms. Emphysema of the skin may also result; on the other hand it may be present without pneumothorax, even in cases of simple fracture of rib, and in cases of interlobular emphysema passing to the neck by way of the mediastinal tissue. In the majority of cases liquid, serous or sero-purulent, accumulates in the cavity; and may often be detected within twelve hours.

The *physical signs* are as follows: the affected side, in valvular cases in comparatively young persons, may be enlarged in girth and of a rounder form. It is, moreover, still in respiration, the half of the chest being fixed (probably in the inspiratory position), or only dragged a little by the efforts of the accessory muscles; the intercostal spaces may fill up; air, like liquid effusion, may press down the diaphragm, thrust the mediastinum aside, and change the place of the heart, liver or spleen. In all cases the lung of the affected side, if free, will tend, of course, to retract, at least to the point of equilibrium of the elasticity. In non-valvular cases the affected side may fall in, so as to be of less girth than the sound side. Vocal fremitus must be absent if the lung be collapsed, or remote from the wall of the chest; if the lung be adherent in part to the chest-wall, vocal fremitus may be so far perceptible, and it may be possible by this sign to map out the extent of the adhesion. Decubitus is usually on the affected side.

Percussion gives us great assistance in the detection of pneumothorax. There is something about

the loud, low-pitched and extensive, if not tympanitic, vibrations of the stricken chest, often extending beyond the normal boundaries of the affected side, which is very characteristic. On the other hand, it is said that if, in valvular pneumothorax, the pleura be tightly distended by air the percussion-note may rise to a high pitch. In these cases a hammer and pleximeter are more effective, though diminished resistance to the finger may be noted. Fluid will dull the percussion considerably or altogether, in districts which will vary with the quantity of it and the position of the patient. In pyopneumothorax, with a bronchial fistula, the sharp line between hyper-resonance and dullness may be changed after a profuse expectoration. In such cases, as in all of free non-valvular opening, percussion is more tympanitic; there is little or no thrusting aside of neighbouring parts. The chest is often retracted. If the opening be large, cracked-pot sound may be obtained. In valvular cases by palpation with percussion dislocation of neighbouring parts and organs may be ascertained. If we confine ourselves to the pneumothorax, auscultation is generally almost negative; in rare cases we may detect by a blowing (amphoric) sound the entrance and exit of air by a free opening. In such cases fluid is always present as well; and a few resonant crepitations may also be heard near the shoulder-blade. The voice-sounds also and the cough may be more or less amphoric. Vesicular breathing is never heard. In pneumothorax there is often present the peculiar epi-phenomenon called *metallic clang*, due to certain inharmonious over-tones, which arise under conditions of which we know little. It never appears at the beginning, and sometimes disappears in the course of a case. After death this metallic echo is always to be obtained. Succussion, known to Hippocrates, is obtained by shaking the patient laterally, when, if free fluid be present, a splash will be heard. The echo of splashing, bubbling, or dripping fluid (*gutta cadens*) in the air-containing pleural cavity, and indeed alien sounds generated inside the patient, such as the heart-beat or cough, may take the metallic clang from the chest-cavity, and may betray pneumothorax or illustrate it. The bell-sound, heard on listening while a bystander taps with a coin another coin laid on the wall of the chest, is well known. Most of these phenomena are best heard by laying the ear on the chest. In the same case, at different times, such sounds may be heard, even at a distance, or may be inaudible—variations which are due to mechanical conditions dependent upon the formation of false membranes, the freedom of the fluid contents, the proportions of the cavity, or the pressure of the contained gases (see PHYSICAL EXAMINATION). In a case of pneumothorax caused in an apparently quite healthy young man during a gymnastic effort, a succession of tinkles was heard, not only by his physician, but also by the bystanders. The sounds, which continued more or less frequently for some little time, seemed to be caused by bubbles of air issuing from the hole in the lung and breaking into the cavity. The patient recovered quickly, and has remained well up to the present time (fifteen years, at least). Finally, in skiagraphy the abnormal clearness of the affected side, the depression of the diaphragm, and the shadow of the retracted lung are manifest, and possibly even waves of succussion.

DIAGNOSIS.—If the presence of adhesions pre-

vent the development of the above symptoms, the case may be more obscure, but by so much the less serious. As, on the one hand, in an enormous moist pulmonary cavity it is conceivable that metallic and succussion-sounds may be heard, so, on the other hand, pyopneumothorax, restricted by adhesions to small dimensions, might simulate a pulmonary cavity. Diagnosis might be impossible in such a case, but, speaking generally, the dullness and retraction of the chest-wall over a cavity would declare the diagnosis. Distension of the stomach with elevation of the diaphragm, or a diaphragmatic hernia, could rarely be mistaken for pneumothorax by anyone who fairly took into consideration all the facts and history of the case. Splashing in the stomach is a much less constant phenomenon, and is obtained by different handling; it varies also in clang. Still, in a particular case of a large stomach suspended by adhesions, some embarrassment arose. A persistence of respiration in the upper part of the chest, signs of mischief below the level of the diaphragm, and perhaps the position of the heart, with the history of the illness, would assist diagnosis. Skiagraphy may help us in such cases of doubt. As empyema, especially in children, may lead to purulent pericarditis, so may pyo-pneumothorax by perforative process have *pyo-pneumo-pericardium* added to it. Emphysema of the lungs may give rise to percussion-sounds of 'horse-hair cushion' quality or as deep as in pneumothorax. Emphysema, however, is practically always bilateral, it is rarely dissociated from signs of open bronchial tubes and vocal vibration is not abolished. In cases of pyo- or sero-pneumothorax there may be a difficulty in determining the quantities of fluid and of gas respectively in the cavity; as much as three quarts of fluid may co-exist with a great deal of resonance above it. Where skiagraphy can be practised, the level of the fluid may thus be distinguished from the abnormally bright air-space above. In emphysema the pulmonary area is abnormally bright on both sides; but in pneumothorax it is still brighter, and is unilateral. The position of the lung also may be perceived. The diaphragm (in cases of high pressure) may be depressed on the affected side. Adhesions may modify all the phenomena infinitely. For the differential diagnosis of subphrenic abscess, often difficult, reference is made to this title. Diaphragmatic hernia (*see* p. 386) presents a curved upper outline, succussion fails, and the history of the case is different.

PROGNOSIS.—This obviously depends so largely upon the causes and circumstances of the pneumothorax that general directions are impossible. The prognosis of chest-wounds, of phthisis, of empyema, contains differences too wide for formulation. The percentage of deaths on the total number of cases is very heavy, perhaps 80 per cent. The tendency of air in the pleura, in the non-valvular cases at any rate, is to absorption. It is asserted that pneumothorax, by sudden oppression of the lung by the indrawn air, may cause rapid or even sudden death.

TREATMENT.—The treatment of pneumothorax must depend greatly upon the nature of the primary malady. Some cases need no treatment at all. To operation in pyopneumothorax from empyema we have referred already. Whether in a case of phthisis pyo-pneumothorax should be dealt with by operation, or not, is a question usually, but not

always, to be decided in the negative. Cases occur in which the pressure or character of the effusion, and the chronicity of the lung-disease, may outweigh the risks; needle-puncture should be tried alone in the first instance. In wounds of the chest-wall, or of the pulmonary pleura, the puncture rarely closes so soon as to imprison the air in a state of higher tension than the atmosphere. In valvular cases the displacement of organs and respiratory distress may call urgently for relief. If so, a fine trocar must be inserted into the chest, and by means of a tube the air and any liquid run off through sterilised water. In such cases with recurrent mischievously high intrapleural pressures, a permanent outward opening with tube and antiseptic dressings may be necessary, in the hope that favourable adhesions may form. Anæsthesia must be local only. The hypodermic use of morphine is not only valuable in soothing the pain and distress of pneumothorax, but also in preventing cough or deep inspirations which, in valvular cases, compel more and more air into the cavity.

4. Pleura, Dropsy of.—SYNON.: Hydrothorax; Fr. *Hydrothorax*; Ger. *Brustwassersucht*.

Hydrothorax is to be classed with dropsies elsewhere, and is often the companion of ascites and anasarca. It may exist alone, but is rarely unilateral. It never exists as a sole malady. We may say generally that it is apt to arise under the following circumstances: when the whole circulation is so impeded that venous pressure is increased, as in heart-disease; when venous arrest is due to some local causes, as, for instance, to the pressure of swellings upon veins, or to venous thrombosis; when the bronchial glands are enlarged; when in renal disease the removal of water from the system is checked and the blood vitiated; or, finally, when the quality of the blood is so deteriorated in the cachexia of cancer or other chronic disease, that its serum oozes from the vessels. In the first and third cases we should expect to find dropsy in both pleural cavities, but such transudations rarely stand at the same height in both; indeed the contents of one of them is often so small in volume that the hydrothorax may seem at first to be unilateral. The right side is generally the fuller, but the difference usually depends upon posture.

DIAGNOSIS.—The diagnosis of hydrothorax and its measure are easy, except in the cases where the effusions are restrained by adhesion. Vesicular breathing may not be absent, as the lung moves more readily than in pleuritic effusion; pressure-signs are rarely observed; the line of dullness does often shift (while in inflammatory effusion it practically does not), and in systemic disease there will be dropsy elsewhere. The pleuritis of arterial and renal disease, often an early event, is unilateral; the effusion contains fibrinous clots, and the pleura is thickened. When hydrothorax co-exists with intrathoracic growths, these signs may not apply, and the needle alone can decide. The fluid is clear, slightly albuminous (2-3 per cent.) and under sp. gr. 1014-17. A higher sp. gr. without fibrin would suggest tubercle or carcinoma. Before assaying the sp. gr. the fluid should stand a while, for coagulation and to let any gases escape from it.

TREATMENT.—Hydrothorax in the majority of cases is not formidable in itself, and (being not uncommonly an event of the last days or hours of life) may be unnoted till the necropsy. Diuretics and hydragogue purgatives act more readily in

hydrothorax than in inflammatory serous effusions; still, if the fluid increase so far as to harass the breathing or to add to the dangers of the disease, it should be drawn away by a fine trocar. The operation may be repeated a great number of times if re-accumulations make it necessary; and sometimes after repeated withdrawals it ceases to recur. In heart-disease or arterial degeneration the transudate is not rarely tinged with blood.

5. Pleura, Hæmorrhage into.—*SYNON. : Hæmothorax.*—Effusions may be bloodstained, as we have said, even in simple pleurisy; but this is more common in such conditions as scurvy, tuberculosis, or cancer. A purely sanguineous effusion is generally the result of wounds of the chest or its viscera; but it may arise from within, as from rupture of a blood-vessel or of an aneurysm, or from a bleeding cancer. The means of examination or treatment of such cases, in so far as these are possible, may be gathered from the preceding sections. Hæmorrhage into the pleura from direct extravasation may be left awhile, on the chance of re-absorption, but if this does not seem on the way, or life be threatened, a tentative puncture may be made, with scrupulous antiseptics. If the issue be ichorous the patient will probably become febrile, and the major operation be needed.

6. Chylothorax.—A very rare event, due to a breach in the thoracic duct, by wound, erosion, or pressure-distension. *Chyliform effusions*, which probably account for nearly all the cases on record, do not contain chyle proper, but are milky from fatty particles and cholesterolin, due to degeneration of cells of pus, epithelium, tuberculosis, or cancer. Such effusions are not very uncommon, and might, of course, have the addition of chyle proper if the duct were perforated. A rapid degeneration of cells, cancerous or tubercular, may give rise to a quantity of fat-droplets so great that a layer of fat may be seen on the top of the serosity withdrawn by tapping. See *FILARIASIS*.

7. Pleura, Morbid Growths in.—Primary cancer of the pleura is infrequent, but the part enjoys no freedom from the invasion of sarcomatous or carcinomatous growths from neighbouring parts, as frequently from mammary cancer, of which it may be the fatal conclusion. It may occur before or after excision. From the cancer in the wall of the chest simple inflammation often extends to the pleura, and produces the ordinary results. In cancer of the lung the pleura, costal or diaphragmatic, is rarely spared, and secondary deposits usually arise, as it were, simultaneously in these parts, and in the pericardium; so that the primary seat may be indistinguishable. Cancer is usually seen in the form of small flattened or rounded elevations, rich in blood-vessels. False membranes in these cases may attain enormous thickness, and friction may be loud and persistent. If septic matters escape into the pleural cavity its effusions, which may be serous, purulent, chyliform (q.v.) or even sero-fibrinous, will soon become putrid. Blood oozes readily from any highly vascular formations—whether cancerous, tubercular, or simply inflammatory; and may be seen in the fluids withdrawn, but a deficiency of fibrin in a hæmorrhagic effusion would suggest cancer.

There is little more to be said of the symptoms and signs of such cases than will be found in former parts of this article; and under *MEDIASTINUM*, Diseases of, p. 967. The diagnosis of cancerous or other such masses from their own effusions, or

from other effusions, may be impossible without the needle, which, if it enter the morbid growth itself, conveys unmistakable information to the finger. A scrap of the growth may be withdrawn. The distribution of areas of dulness in cases of morbid growth often enables us to distinguish them from cases in which the anatomical boundaries of the chest are respected, or the action of gravitation unimpeded. Enlargement of tracheo-bronchial glands may be detected beneath the sternum or in the interscapular space; or again in the supraclavicular fossa, from which latter they might be removed and examined microscopically. Fever is usually but by no means always absent. Still after all in most cases early diagnosis is difficult.

The prognosis will not depend upon the pleuritic changes; and the only remark to be made on the treatment is that paracentesis, in the secondary effusions, is not wholly to be declined. Some patients have obtained from repeated puncture perhaps a prolongation of life, certainly a relief of suffering. If in case of doubt the removal of a substantial effusion give little or no relief, morbid growth may be suspected.

Hydatid of Pleura.—Hydatid is rarely met with in England either in pleura or lung, and in either occurs rather as a secondary than as a primary event. The most common source of thoracic hydatid is the liver, whence it tends to invade rather the right side of the chest, and may rise nearly to the clavicle. In some cases, when the cyst is comparatively small and unbroken, its nature may be suspected from its position and outline.

In other cases, and especially if the cyst has ruptured into the pleural cavity, physical diagnosis may give no conclusive evidence, and we must make what we can of the history and other circumstances of the case. The fluid is non-albuminous, of low sp. gr., and contains hooklets (p. 462). The occurrence of pain suggests pleural relations.

When a hydatid cyst breaks into the pleural cavity, its treatment falls under the ordinary rules of pleuritic effusion, but aspiration alone will not suffice for a cure. T. CLIFFORD ALLBUTT.

PLEURA, Surgery of.—The operations upon the pleura fall naturally into two groups, those undertaken (1) for purposes of diagnosis, and (2) for purposes of treatment.

1. For purposes of Diagnosis.—The best instrument is a large hypodermic syringe that can be rendered absolutely aseptic. The needle is thrust through the middle of an intercostal space at a spot which is well within the limits of the area suspected to cover a collection of fluid. In cases where the patient is very nervous and apprehensive of pain, the skin should be frozen at the spot selected for the insertion of the needle. Inasmuch as the pain is so slight and momentary, it is justifiable to treat the apprehension of the patient by suggestion, and to wipe the area of skin with a substance which the patient is told will prevent the pain. To inject any local anæsthetic would cause almost as much pain as the exploring needle itself. If no fluid escapes into the syringe as the piston is pulled back, the depth of the point of the needle from the surface should be gradually varied. If the result be still negative the syringe should be detached from the needle and the latter cleared by means of the usual stylet; the syringe is then attached again and another attempt made at

the same spot. It is usual to insert the needle in several places, say three or four, until a positive result is obtained. If the needle and syringe have been cleaned out with carbolic-acid lotion and several drops of this fluid have remained in the syringe, this may cause coagulation of any albuminous fluid in the lumen of the needle, and thus plug the passage. Another important drawback to the use of carbolic-acid lotion is that even if fluid is found it may be altered in appearance by mixing with the carbolic-acid lotion; thus, to a somewhat inexperienced eye, a few drops of serous fluid mixed with a drop or two of carbolic lotion, may present the appearance of pus. If it be thought best to cleanse the syringe with carbolic lotion, it is important to finish the cleansing with some boric-acid solution or a little boiled water.

At the present day the treatment of pleuritic effusions depends to a large extent upon the kind of micro-organism producing the inflammation, and therefore it is most important to ascertain what micro-organism, if any, there is in the fluid. If suitable sterilised tubes with nutritive media are to hand, the inoculation should be made at once direct from the syringe. If, however, the fluid has to be sent some distance it should be emptied from the syringe into an empty sterilised test-tube, or the needle itself be sealed with wax and surrounded with aseptic wool or lint, and sent to the bacteriologist without delay. Owing to the fact that tubercle-bacilli are often absent in effusions from a tuberculous pleura, or at any rate owing to the fact that the tubercle-bacillus cannot be demonstrated, inoculation of guinea-pigs may be the only certain means of diagnosis; definite instructions should therefore invariably be sent to the bacteriologist as to the nature and source of the fluid and the exact information required.

2. For purposes of Treatment.—The pathological condition demanding operative interference is the presence of fluid in the pleural cavity which either by its quantity or its toxic action is producing mischief. Broadly speaking, there are two kinds of fluid which are met with: (1) Clear or slightly turbid, as met with in ordinary 'pleurisy with effusion'; and (2) thick or purulent, varying in consistence and appearance according to the nature of the disease.

It is not within the province of this article to discuss the indications for deciding upon any definite line of treatment.

The methods used for evacuating pleural effusions are aspiration and incision with drainage.

(A) *Aspiration of the Thorax, Thoracocentesis.*—An enormous variety of apparatus has been devised for this purpose; most of the instruments aim at emptying the pleural cavity as completely as possible in one operation. Of recent years various methods for permanent aspiration have been devised and used with considerable success, especially on the Continent. In Great Britain simple aspiration, removing as much fluid as possible at one sitting, is the usual practice. The condition of the patient must be carefully watched, and the withdrawal of fluid stopped the moment the patient shows any signs of collapse. The fluid should be removed slowly and, according to some authorities, never more than 50 oz. should be removed at one sitting. The criterion as to the amount that can be removed at one time really depends upon the condition of the patient, which must be most

carefully watched. At the London Hospital Dieulafoy's aspirator is the one in general use. It is unwise to employ an apparatus where any marked degree of forced aspiration is used. Other well-known apparatus are Potain's aspirator and its various modifications, especially that by Debove, in which all stopcocks are done away with. See ASPIRATOR.

Operation of Thoracocentesis.—The spot for aspiration having been selected, the skin is well cleaned and rendered aseptic. If the collection of fluid is considered by the physician to occupy the whole pleural cavity the exact point for aspiration is usually left for the surgeon to decide upon. The consensus of opinion seems to be that the best spot is a point in the mid-axillary line between the fifth and sixth ribs. Next in favour to this point is a spot below the angle of the scapula in the seventh or eighth intercostal space. Any point lower than this should be avoided so as not to wound the diaphragm or the abdominal organs, and to avoid the needle getting blocked by the rising of the abdominal organs as the chest becomes more and more empty of its fluid. The patient should lie on his back in as horizontal a position as possible. At the commencement of the operation the patient's dyspnoea may be so great that he can only breathe in a sitting posture. As the aspiration continues and the dyspnoea is relieved, the patient should gradually be allowed to assume the horizontal position, so as to avoid syncope. When it is decided that sufficient fluid has been removed, or when no more fluid can be obtained, the needle should be rapidly withdrawn and the puncture sealed with a little collodion.

In order to remove all the fluid from the pleural cavity, a procedure which seems to the writer to be absolutely unnecessary, methods have been used by which sterilised air is forced into the pleural cavity so as to completely empty it of effusion. Not only does this method seem unnecessary, but it may be distinctly harmful. To subject an inflamed surface of considerable area to sudden changes of pressure certainly seems unwise.

A method of *permanent aspiration* has been devised by Playfair and by Bulau. The skin is rendered anæsthetic, and a large trochar and cannula is pushed through one of the lower intercostal spaces. After removal of the trochar a soft india-rubber tube is pushed through the cannula into the pleural cavity and then the cannula is withdrawn. This tube is fixed to the skin by a couple of stitches, and is connected with a vessel containing an antiseptic solution. In order to see the exact nature of the fluid a glass junction is inserted. The patient can walk about with the bottle in his pocket. Very favourable reports on this method come from the Continent, but it does not appear to have been employed on any large scale in this country.

At the present time the operation of thoracocentesis is limited to removing serous effusions and the purulent effusions of tubercular disease. Practically in all cases of pyogenic infection the operation of incision and drainage is the one employed.

(B) *Method of Incision and Drainage, Thoracotomy.*—For the removal of purulent collections from the chest this operation has been practised on and off since the days of Hippocrates. There has been a tendency to lay too much stress upon the difficulty of this operation. Practitioners with but little familiarity with surgical procedures

sometimes delay in dealing with an empyema, because they are afraid to push a scalpel between two ribs, and, by postponing the operation, imperil the lives of their patients.

Operation of Thoracotomy. — At the outset we meet with the question as to whether it is advisable or necessary to remove a portion of rib or whether a simple incision through an intercostal space into the cavity is alone sufficient. The general consensus of opinion seems to be that the removal of a portion of rib facilitates drainage and assists in the falling in of the chest-wall, which is one of the essential features in the final closing of the cavity. The operation should be performed under strict antiseptic precautions. Every effort should be made to prevent the entrance of ordinary pyogenic organisms from without. The empyema may have been caused by micro-organisms whose activity is practically exhausted, or which rapidly die when disturbed by drainage, or a mistake may have been made and a tubercular cavity opened.

An incision three inches long is made over the seventh rib, in the posterior axillary line. The periosteum is incised and reflected to the upper and lower borders of the rib and detached carefully with the intercostal muscles. When isolated the rib is divided with bone-forceps and about two inches of it removed. The thickened pleura is then incised parallel with the intercostal incision and the pus evacuated. Any large masses of coagulated exudation presenting at the aperture should be seized with forceps and pulled out. The patient is usually coughing at this stage, and the masses are jerked against the opening with each expiration. Owing to the fact that a sudden stoppage of the heart has followed flushing of the cavity it is wiser not to do this, but having evacuated as much of the pus as possible a drainage-tube should be inserted. Effective means should be taken to prevent the tube slipping into the cavity. One of the best ways is to transfix with a large safety-pin the outer end of the tube. An antiseptic dressing is then applied, and as soon as the discharge soaks through it should be replaced by another. In all cases the tube should be shortened in a few days, and in very favourable cases, where the lung has expanded rapidly and where little or no pus escapes, the tube should be removed and a small gauze drain inserted.

The closing of an empyema-cavity is due to three causes: (1) The expansion of the lungs; (2) the falling in of the chest-wall; and (3) the conversion of the granulation-tissue lining the lung and the parietal pleura into cicatricial tissue. This still further helps in expanding the lung and pulling in the chest-wall. In certain cases these three factors are insufficient to close the cavity, and a very awkward condition is arrived at, especially when the cavity may measure in its three planes respectively, eight or nine inches, four or five inches, and two or three inches. This means a very large superficial area of granulation-tissue, generally septic and discharging many ounces of pus each day. To Estlander is due the credit of first dealing effectively with this condition; recognising that nothing could be done to cause the lung to expand and that the rendering of the cavity aseptic, when possible, is of no avail, there remained naturally the chest-wall to deal with. In order to facilitate the falling in of the chest-wall he excised several inches

of several ribs so that there was an immediate, and afterwards a gradual, approximation of the chest-wall to the lung.

As regards the operative procedure each case must be considered on its merits, and it is here that the experience of an operating surgeon is essential. The operation may be a very extensive one, requiring high surgical skill for its proper performance. The details of such operations do not come within the scope of this work.

HENRY PERCY DEAN.

PLEURODYNIA (πλευρά, the side; and δόνη, pain).—SYNON.: Intercostal Myalgia; Fr. *Pleurodynie*; Ger. *Seitenschmerz*.—A name for muscular rheumatism or cramp affecting the chest-wall. See CHEST-WALLS, Morbid Conditions of; CRAMP; and RHEUMATISM, MUSCULAR.

PLEURO-PNEUMONIA. — This compound word signifies a combination of inflammation of the pleura and of the lung itself. In all cases of acute pneumonia there is a certain degree of pleurisy corresponding to the inflamed lung; but it is of little or no practical significance, there being only some exudation on the pleural surfaces. Pleuro-pneumonia implies that the two morbid conditions are actually associated in various degrees, giving rise to their respective pathological changes, and each thus influencing the symptoms and physical signs. Individual cases, therefore, present many diversities, in accordance with the different ways and degrees in which the two diseases are combined. It may happen that they are associated from the first; or one may supervene during the progress of the other, in this way modifying its course and physical signs, and not uncommonly rendering the diagnosis more or less obscure and difficult. See LUNGS, Inflammation of; and PLEURA, Diseases of. FREDERICK T. ROBERTS.

PLEUROTHOTONOS (πλευρόθεν, laterally; and τόνος, tension).—A form of tetanic spasm, in which the body is bent towards one side. See TETANUS.

PLEXIMETER (πλήσσω, I strike; and μέτρον, a measure).—A flat instrument used in mediate percussion, by being applied to the surface of the body to receive the stroke of the plessor. See PHYSICAL EXAMINATION.

PLOMBIÈRES, in France.—Thermal waters, with some soda, silicate, and arsenic. See MINERAL WATERS.

PLUMBISM. — See LEAD-POISONING; and OCCUPATION-DISEASES.

PNEUMATOCELE (πνεύμων, the lung; and κύλη, a tumour).—Hernia of the lung. See LUNGS, Malpositions of.

PNEUMOCONIOSES (πνεύμων, the lung; and κόνις, dust). — By the term 'pneumoconioses' is meant diseases of the lung due to inhalation of dust. Upon the character of the dust depends the rapidity with which the lung-tissue is destroyed. The dust given off from stone and steel during grinding is hard and angular and is therefore much more harmful than soot or coal-dust, which is soft and less angular. Mineral, metallic, or organic particles when inhaled into the pulmonary alveoli are capable of causing chronic inflammation.

Anthracosis (*ἀνθραξ*, a burning coal).
SYNON. : Coal-miner's Phthisis. — Until coal-mines were ventilated according to the regulations laid down by Act of Parliament, colliers, as a class, suffered much from bronchitis and phthisis, but so effectively is fresh air carried into the furthest recesses of mines and the foul air removed that the coal-miner of to-day enjoys an immunity from phthisis which is denied to the general population. It is the exception now to find coal-miners suffering from consumption. Although the 'black spit' is a thing of the past, the lungs of colliers are found after death to be deeply pigmented without any pronounced pathological changes. The human lung is wonderfully tolerant of coal-dust and the soot from the miner's lamp.

ANATOMICAL CHARACTERS.—The lungs, which may or may not be adherent, are frequently emphysematous and bluish-black in appearance, and through the pleura can be seen and felt small black nodules. The glands at the root of the lung are enlarged and on section black. On cutting the lung there escapes on pressure a black inky fluid which stains the fingers, and the pulmonary tissue is black. The lungs are usually not diminished in size, for carbon-particles when inhaled do not induce fibrotic change like some other forms of dust. On microscopical examination the black particles are seen along the lines of the lymphatics. It is upon the mucous membrane of the bronchi that the particles of coal-dust first fall when inhaled. Here they may be taken up by the epithelial cells and thrown out by the expectoration. Some may penetrate the bronchial mucous membrane, but it can only be a few on account of the thickness of the basement-membrane. What causes the dark pigmentation of the lung is the particles that have been aspirated into the alveoli. There they effect an entrance into the lymphatics by passing between the epithelial cells or through stomata, and they subsequently come to occupy the lymphatics that are distributed around the branches of the pulmonary artery. Most of the black nodules observed on cutting a lung are perivascular accumulations of carbon-particles. In a similar way they also surround the bronchi or appear as long streaks in the pulmonary septa. Thus is explained the generalised pigmentation of the lung. In the bronchial glands to which the lymphatics run the carbon-particles are arrested. In the absorption and conveyance of the pigment, leucocytes probably play an important part.

SYMPTOMS.—It was formerly held that *anthracosis* and *tubercular phthisis* were naturally exclusive of each other. There is nothing to support this contention. In all the pneumoconioses, destructive processes in the lung are induced in the first instance by irritating particles, but in the pulmonary lesions thus induced tubercle-bacilli may subsequently find a suitable nidus. It is only because coal-dust particles are little irritating and the collier works in very pure air that anthracosis is not more frequent. Once the disease is established it runs a slow course. The individual gives a history of recurrent attacks of bronchitis attended by cough and dyspnoea on exertion. His expectoration is black. When upon a lung in this condition there is engrafted tubercular infection there occur the progressive emaciation, failing health and more abundant expectoration observed in ordinary phthisis.

Lithosis (*λίθος*, a stone).—**SYNON.** : Silicosis

(*silex*, flint); Stonemason's, Stonegrinder's and Potter's Phthisis.

The dust given off by stone and by fired clay is composed of silica or silicate of alumina. As the anatomical changes in the lungs in stonemotters and potters are practically the same, one brief pathological description will apply to both. Particles of silica are extremely irritating and destructive to lung-tissue. Their presence in the lung induces a reactive inflammation which is followed by an excessive development of fibro-connective tissue. The lung subsequently contracts, is hard and on section feels gritty, but it may be bulky if the amount of stone-dust contained is large. Hard nodules of dense fibrous tissue are often present, and in these can be seen and felt particles of grit. At places the pleuræ are densely adherent, while at others there can be seen projecting through the pleuræ similar nodules to those just mentioned. The particles of grit observed on section of a fibrotic area do not dissolve on the addition of an acid. Greenhow found on incinerating a portion of cirrhotic lung and boiling the ash with strong hydrochloric acid that none of the ash was dissolved, and that the residue, which was composed of minute angular particles, disappeared on exposure to the fumes of hydrofluoric acid, a circumstance that showed the particles to be silica. Owing to retraction of the fibro-connective tissue bronchiectatic cavities are formed in the lungs. The bronchial glands are much enlarged and extremely hard, and on section exhibit a greyish-black colour. The lungs may show patches of catarrhal pneumonia. Commencing as a non-tubercular disease tubercle-bacilli may ultimately be found both in the expectoration and in the lung. Sometimes the lungs of lead-miners become stonily hard, solid, and heavy: the parenchyma becomes replaced by dense fibro-connective tissue and assumes a bluish-black appearance, but on chemical examination of the lung the writer has never found lead therein, a circumstance which shows that just as in the stonemason's and potter's lung the cirrhosis of the organ is caused by particles of stone (*lead-miner's phthisis*).

It is interesting to note that the granite-workers of Aberdeen do not suffer from pulmonary phthisis in consequence of their occupation. Hamilton attributes this immunity to the igneous origin of the stone, the larger size of the particles, and the fact that they do not reach the pulmonary alveoli, as they become entangled in the upper parts of the respiratory passages. Of all stone-cutting and stone-dressing occupations, one of the most un-healthy is French grindstone-building. 'Buhr' stone is extremely hard. It is chiselled into wedges which are placed together to build up a grindstone. The men who follow this employment die in very large numbers. Peacock estimated the mortality from lung-disease to be 40 per cent., and that the average age at death of 23 labourers out of 41 was 24·1 years. The writer has visited most of the 'buhr' stone-yards in the country and examined the men who work therein, and can bear testimony to the views just expressed. The men are short-lived, they seldom reach the age of 35, most of them dying much earlier. They may follow their occupation for five or ten years without feeling any bad effects, and then without any special explanation they begin to suffer from cough and profuse hæmoptysis. The illness runs a very rapid course. A considerable number of ordinary stonemasons,

too, seek relief on account of pulmonary disease by the age of 35-40.

Potter's Rot or Asthma.—The manufacture of china and earthenware is a prolific cause of pulmonary disease, owing to the clay and flint used in their production. The clay is rich in siliceous material. To it and the sharp angular particles of flint is attributed, when inhaled, the damage done to the lung which causes *potter's rot*. Of all the processes the one most responsible for pulmonary disease is the 'scouring,' or brushing off the dust from the china after it has been fired. A dustier process is scarcely conceivable when done by hand. The work is generally done by women who are ignorant and careless. Owing to the hard and penetrating character of the dust considerable injury is inflicted upon the lung. Its power for harm is only surpassed by the dust given off in the Sheffield dry-grinding trades. The disease it causes develops slowly, at first without any constitutional symptom, for it is a non-tubercular process. There are morning cough, shortness of breath, and mucous expectoration; but, unlike the French millstone-builder, hæmoptysis is usually absent from first to last. So insidious is the malady in its inception that, as the appetite remains good and the worker looks and feels well for a lengthened period he continues to follow his employment, thus exposing himself to further pulmonary implication. For a period he expectorates white frothy material containing a few black streaks due to the presence of dust, but as time goes on the sputa become purulent, the cough more paroxysmal and violent, and the dyspnoea even greater than in ordinary phthisis and out of all proportion to the amount of consolidation of the lung. It is less the apices than the bases of the lungs that are affected. Here and there in the chest patches of alternate dulness and resonance may be detected due to consolidation and emphysema respectively. The disease differs from ordinary tubercular phthisis in its extreme chronicity and in the fact that the apices are much less involved. The patient retains the look of an asthmatic rather than that of a consumptive. The potter thus affected suffers like the victim of chronic bronchitis from dilatation of the right heart with its attendant troubles. Arlidge found, over a series of years, that the mean age at death of male potters aged 20 and upwards was $46\frac{1}{2}$ years, while that of non-potters stood at 54; that potters had a mortality of 12.29 per cent. compared with 7.86 of other workpeople; and as showing how one branch of the industry was more deadly than others, phthisis was the malady in 40 per cent. of china-scourers, and bronchitis in 25 per cent.

Closely allied to potter's rot is the condition which is prevalent among workers in asbestos-factories.

Steel-grinder's Phthisis.—So far as the Sheffield trades are concerned it is the 'dry' grinding that is most provocative of disease. Some of the very fine particles of steel and stone-dust given off during this operation are inhaled by the workman, who, sitting astride his 'horse,' bends closely over the wheel upon which the grinding of scissors and razors is being conducted. Sooner or later, as the result of the inhalation of dusty particles, a considerable amount of tracheal and laryngeal irritation is induced, the voice becomes husky and there is cough, accompanied at first by very little expectoration. Subsequently there are superadded to the

cough dyspnoea on exertion, pain in the chest, muco-purulent expectoration, progressive emaciation, and all the signs and symptoms of pulmonary phthisis with recurrent hæmoptysis, a circumstance which causes steel-grinder's rot to differ symptomatically from the similar lung-affection of the potter. The fibrotic changes in the lungs of steel-grinders have been attributed by some writers to iron-dust, but the amount of iron found in the lung is really small compared with silica. It is more than probable, therefore, that they are due to particles of the grindstone given off during dry-grinding, for this operation is always more harmful than the wet process.

Basic Slag.—When ground, the basic slag obtained from iron-works is used as a manure. The pulverisation of it is a very dusty process. The dust itself is not poisonous, but when inhaled it has a decidedly deleterious influence upon the respiratory organs. Many of the workmen suffer from cough, and have deep husky voices. They become bronchitic and the subjects of emphysema and asthma. They die of pneumonia in a larger proportion than men engaged in other occupations. Once an acute or sub-acute pulmonary disease is superadded to the bronchitis, the illness runs a more rapid course than a similar malady established in men engaged in other dusty trades. This, however, may be partly due to the intemperate habits of the workmen. Time is not usually given for fibrotic changes to occur in the lungs. Within the last few years, owing to improved machinery and the fact that the grinding is conducted in closed mills, there is much less illness among the men than formerly.

Ganister Disease.—Ganister is a siliceous rock found in the under-clays of the lower coal-measures, and when made into bricks is used to line the bottom of Bessemer-steel converters. It is an extremely hard substance. The men who mine and grind the ganister, also those who make it into bricks, owing to the very dusty nature of the operations and the extremely hard and sharp character of the particles, soon become incapable of any lengthened physical exertion. They develop a hacking cough and in four or five years' time die from fibrosis of the lungs. Birmingham found the average annual death rate from lung-disease in ganister-workers to be 22.29 per 1,000, and Robertshaw that the average age at death was 36.6 years. The symptoms at first are those of bronchitis from mechanical irritation, but eventually there is induced fibrosis of both lungs.

In Siderosis (*σίδηρος*, iron) the structure of the lung is altered by iron dust that has been inhaled. The disease occurs in colour-grinders and makers, who use oxides of iron. It was the detection of the red oxide of iron in the lung by Merkel that definitely proved the pathological changes in the lung to be due to varying kinds of particles inhaled. Siderosis runs a much more rapidly fatal course than many forms of pneumoconiosis. It may cause death in two years, the symptoms being those of rapid phthisis with hectic fever. At the autopsy the lungs present a bright red colour, contain a few nodules or small cavities and are otherwise similarly affected as in silicosis generally.

Cotton, Flax, and Flour-dust.—*Cotton.*—Both in opening the compressed bales of raw cotton and during the manufacturing processes known as 'scutching' and 'carding,' that have for their

object the removal of impurities and the conversion of the fibre into fluff ready for spinning, there is a considerable amount of dust given off which when inhaled causes irritation of the naso-larynx and the mucous membrane of the bronchi. The voice becomes husky and there is cough with expectoration. Cotton-fibres may be detected in the sputa on microscopical examination. Fibrosis of the lung is occasionally established and the case becomes one not unlike ordinary phthisis. In some of the cotton-manufacturing districts the mortality among the workpeople is as high as 9 per 1,000 or 1,088 as against 1,000 employed in other occupations.

Apart from the inhalation of dust and fluff, workers in this particular industry are exposed to the possibility of pulmonary disease from adulteration of the cotton. In order to give tenacity to the thread the material is 'sized,' i.e. passed through a mixture of china clay, such as is used in the manufacture of earthenware. This immersion not only aids the weaving of the cloth, but by adding materially to its weight becomes an adulterant. During the process of weaving it becomes absolutely necessary to have the air of the factory at a high temperature and moist. This artificial atmosphere produces in the workpeople languor, loss of appetite, and anæmia. The vital resistance is reduced, and there is a predisposition to catch cold more readily. The factory hand thereby becomes an easier prey to the irritating china-dust that is given off from the sized cotton, and not infrequently falls a victim to phthisis.

Flax.—During the process of 'scutching' there is given off from flax a fine dust that is even more irritating than that from cotton. Purdon found that workers in the linen-mills of Belfast suffered in large proportion from dry throats, cough, and expectoration often tinged with blood, and that many of the cases terminated in true tubercular phthisis to the extent of 6 per 1000.

Flour-dust.—In the milling of wheat by the old methods of horizontal stones a considerable amount of dust is given off, so that men working in the cloudy atmosphere suffer from pulmonary phthisis far in excess of the ordinary male population. The danger of flour-dust is not so much that it is irritating to the bronchial mucous membrane, as that it is apt to form tenacious plugs, requiring strong expulsive efforts of coughing to dislodge them. Pulmonary emphysema is apt to be induced under these circumstances. In addition to the grains of flour there are given off irritating particles of siliceous dust, owing to the wear and tear of the millstones, particles of hair and bran from the grain, especially oats, so that pathological changes are set up in the lungs, that lead to phthisis. Of one hundred millers, Hirt found that ten were the subjects of pulmonary consumption. Since the introduction of the steel-roller method, the grinding of wheat is conducted within closed chambers, so that the air of a flour-mill is no longer made thick with dust, but is, comparatively speaking, clear. The result of the new method of milling is that pulmonary phthisis has practically disappeared from this industry.

PREVENTION.—If an illustration were required to show how occupational phthisis can be prevented allusion need only be made to coal-mining. Formerly consumption and other forms of pulmonary disease were extremely prevalent among coal-miners, but to-day, thanks to the excellent

system of pit-ventilation, they are seldom observed. Since the various forms of pulmonary disease above alluded to are largely due to working in places where the atmosphere is thick, and to the inhalation of particles of dust, it is clear that much of the illness can be prevented by removal of the dust, by improvement of the ventilation of the workshops through the use of fans and down-draughts, and by the substitution of wet for dry processes of production wherever practicable. Repeated floor-sweeping and the sprinkling of the floors with water during meal-hours should be attended to. In dusty operations the workpeople should wear respirators. Persons of a scrofulous habit, or members of a consumptive family, should not continue to work at a dangerously dusty occupation, but retire and seek employment out of doors. Unfortunately, however, in most of the cases the symptoms do not show themselves until the disease is pretty well established.

SYMPTOMS.—The earliest symptoms are cough, due to laryngeal irritation or spasm, and dyspnoea due to emphysema or other destructive processes in the lung. There is at first expectoration of mucus that is often coloured with the dust that has been inhaled, but later on it becomes muco-purulent. In some of the pneumoconioses hæmoptysis is present, in others it is absent. In the terminal stages tubercle-bacilli may be found in the sputa. The physical signs are those of emphysema of the lungs in some, of induration, excavation and retraction in others. As the malady advances emaciation becomes progressive, and the patient often dies from hectic fever. The disease proceeds so very slowly as a rule that the patient continues to follow his employment for years. On the other hand, it may be that life is quickly terminated by recurrent hæmoptysis and its consequences, or by the super-vention of acute pulmonary inflammation.

TREATMENT.—Removal of the patient from his occupation at once suggests itself; and if the illness is only commencing good may follow this procedure. Too often the pulmonary damage already inflicted is too great to be thus arrested. The treatment under these circumstances becomes therefore one of symptoms, and is practically the same as that for tubercular phthisis, viz. expectorants to relieve cough, tonics to improve the appetite and general health, cod-liver oil to help nutrition, and as far as possible life in the open air.

THOMAS OLIVER.

PNEUMOGASTRIC NERVE, Diseases of.—

SYNON. : Fr. *Maladies du Nerf Pneumogastrique* ; Ger. *Krankheiten des Vagus*.—Of all the cranial nerves, the pneumogastric has the most extensive distribution, supplying the pharynx, larynx, lungs, heart, œsophagus, and stomach, and even, in part, the intestines and the spleen. In some of the so-called functional diseases of the organs which it supplies its action is conspicuously deranged. The symptoms of its disease are thus very extensive, and it will be well first to describe them generally, and afterwards to consider in detail those which merit separate description.

Some of the functions of the vagus depend upon fibres of the spinal accessory nerve which join it, but it is convenient to consider these in this article.

The pneumogastric nerve, it will be remembered, arises from the side of the medulla, between the glosso-pharyngeal above, and the spinal accessory

below, and to the outer side of the hypoglossal. The fibres of origin come from a tract of grey matter which is continuous below with the nucleus of the spinal accessory, and above lies (in the *calamus scriptorius*) between the hypoglossal and internal auditory nuclei, while to the outer side of its upper extremity, and more deeply seated, is the nucleus of the glosso-pharyngeal. The trunk of the nerve, after receiving fibres from the spinal accessory, and giving off some small branches (of which the most important is one to the external ear), passes down the neck, behind, and in the same sheath with, the carotid artery; enters the thorax on the right side, over the subclavian artery, and, on the left, between the subclavian and the carotid; passes through the thorax beside the oesophagus; and ends in branches to the stomach, spleen, and intestines. The most important branches are the pharyngeal, which, with the glosso-pharyngeal, form the plexus of the same name; the superior laryngeal; the recurrent laryngeal, which passes back, the left around the arch of the aorta, the right around the subclavian artery; branches to the oesophagus; pulmonary branches which, by means of the pulmonary plexus, supply the lung; and branches which form the cardiac plexus for the heart.

ÆTIOLOGY.—The deep position of the pneumogastric and its branches preserves it from some forms of damage, although its extensive course renders it liable to suffer from many causes. The nucleus in the medulla may be damaged by local softening, hæmorrhage, or slow degeneration; but in all these cases other adjacent nuclei suffer (*see LABIO-GLOSSO-LARYNGEAL PARALYSIS*). The nerve, at its origin from the medulla, may be compressed by thickening of the meninges, growths from the meninges or bones, or aneurysm of the vertebral artery. Affections of the nerve due to syphilis are almost always the result of meningeal disease in this situation. Other adjacent nerves commonly suffer at the same time. The trunk of the nerve is sometimes, but rarely, implicated in punctured or gunshot wounds; incised and lacerated wounds damaging it are usually immediately fatal from lesion of the large blood-vessels to which it is contiguous. In surgical operations the trunk and branches of the nerve are occasionally injured. The trunk has been tied in ligature of the carotid, and divided in the removal of deep-seated tumours. In such operations in the lower part of the neck it is often difficult also to avoid injury to the recurrent laryngeal. In excision of an enlarged thyroid both recurrent laryngeal nerves have been many times excised. Sarcomatous and other tumours, and enlarged glands, may compress or involve the nerve in almost any part of its course; and interference with its function especially occurs from such disease in regions limited by rigid structures, as in the upper part of the neck, near the skull, and in the upper part of the thorax. Aneurysms may compress the nerve or its branches; and the recurrent laryngeal nerves suffer from this cause with especial frequency, because they pass round large blood-vessels. The left suffers much more frequently than the right, because the arch of the aorta is more frequently affected by aneurysm than the subclavian. An enlarged thyroid may compress the recurrent laryngeal nerves, and symptoms due to such compression may vary with the varying size of the tumour. The nerve is, in rare cases, the seat of neuromata. Neuritis of the trunk of the nerve, due to cold, is

supposed to be an occasional cause of symptoms, but such cases are extremely rare. It is sometimes involved in very severe and grave cases of multiple neuritis, especially that due to diphtheria and to beriberi.

SYMPTOMS.—It must be remembered that the vagus nerve, besides containing motor fibres for the pharynx and larynx, is the chief afferent nerve for the respiratory centre. It contains accelerating and inhibitory fibres for this centre, but the former predominate, so that experimental division of the nerve in an animal renders the respirations less frequent but deeper, while stimulation of the divided (central) end quickens the respiration, and may even arrest it in tetanic standstill. The inhibitory fibres are contained chiefly in the superior laryngeal nerve, and their stimulation arrests the respiration in muscular relaxation. The vagus is the inhibitory nerve of the heart; slight stimulation increasing the diastolic periods, and stronger stimulation arresting the action of that organ. On division of the nerve the cardiac contractions are accelerated. It has been said to contain trophic fibres for the heart and lungs. The pneumogastric is an afferent nerve for the vasomotor centre, the action of which is lowered by its stimulation, so that the arteries throughout the body are relaxed. It is the motor and sensory nerve for the oesophagus; the sensory nerve for the stomach; and partly also the motor nerve for the stomach and intestines.

Symptoms due to paralysis of the vagus are more frequently met with than those which result from its irritation. Occasionally both are combined. Laryngeal spasm and vomiting are the irritative symptoms most commonly met with, but occasionally cardiac inhibition occurs. Czermak, for instance, was able to arrest his heart for a few beats at will, by pressing a small tumour of the neck against his pneumogastric. Concato had a patient in whom a similar inhibition could be caused by pressure on the right nerve. The increased frequency of pulse which corresponds to paralysis of the nerve has been several times noted, and has occasionally been associated with diminished frequency of respiration, although the laryngeal paralysis, also resulting, has often obscured the effect on the respiratory movements. Roux tied the trunk of the vagus with the left carotid; instantly respiration was arrested, but the pulse was also retarded. The ligature was immediately relaxed, but the patient died in half an hour. Robert also tied the nerve with the carotid; the patient, who was conscious, immediately called out, 'I am suffocated!' and his voice became hoarse. He recovered, but the hoarseness continued for six months. A good example of interference with the functions of the vagus has been recorded by Guttman. A lad, after diphtheria, presented paralysis of the palate and of one sterno-mastoid. His respiration quickly became reduced to 12 per minute, and very laboured, while his pulse rose to 120, and he died in a few hours. In many other cases a similar change in the pulse and respiration has been noted, and even a pulse-rate of 160–200. In the face of these observations, and of experiments on animals, it is not easy to understand a fact, said to have been observed by Billroth, who excised half an inch of one pneumogastric, which was implicated in a tumour, without any resulting symptoms.

The important central relations of the vagus, above alluded to, cause its derangement to form part of many so-called functional disorders of the central nervous system. Its nucleus forms part of, or is connected with, the respiratory centre, which is conspicuously disturbed in hydrophobia and some other diseases. The phenomena of 'Cheyne-Stokes breathing,' or 'respiration of ascending and descending rhythm,' are probably the result of lowered action of the respiratory or pneumogastric centre (*see* RESPIRATION, Disorders of). This symptom is met with in cerebral hæmorrhage, uræmia, meningitis, and in some cardiac diseases. The central connections of the vagus, in the hemispheres, extend to, or are connected with, those parts which are concerned in emotion, and it is probably through the agency of this nerve that the heart's action is affected in excitement and fear. In many epileptic fits the central representations of the nerve are the parts through which the consciousness is first affected, and hence the so-called 'epigastric aura,' which may seem to ascend to the throat.

A similar disturbance is in all probability the cause of the globus hystericus and of the laryngeal spasm, which are conspicuous in some epileptic and hysteroid seizures. The nerve is closely connected with the centre or nerves for equilibration, so that severe vertigo, on whatever dependent, is often followed by vomiting. The pneumogastric nucleus is contiguous to the internal auditory nucleus, and in the vertigo which results from disease of this nerve, or of the semicircular canals (labyrinthine or aural vertigo), vomiting is very common. The nausea and retching of sea-sickness are probably due to the deranged action of the semicircular canals, in consequence of the motion of the endolymph disturbing their nerve-endings, which in turn affect the pneumogastric centre. It is possible that the connection of the vagus with the equilibratory nerves is by means of the cerebellum, disease of which so constantly causes vomiting, although this connection has not yet been traced. Conversely, gastric disturbance of the vagus is often accompanied by vertigo, especially when combined with pre-existing imperfect action of the auditory nerve.

1. Pharyngeal Branches.—The branches of the pneumogastric which enter the pharyngeal plexus supply the constrictors of the pharynx and the soft palate. Some have asserted that all the pharyngeal branches are derived from the spinal accessory. The branches to the soft palate are certainly derived from the spinal accessory. When one vocal cord is paralysed from disease of the roots of the spinal accessory, the levator palati on the same side is, as a rule, also paralysed, and very often there is palsy of that side of the tongue from damage to the adjacent roots of the hypoglossal nerve. *See* PALATE, Paralysis of.

(1) Paralysis.—**ÆTIOLOGY.**—The most common cause of paralysis of the pharynx is disease of the origin of the nerve in the medulla; such disease commonly also involves adjacent nuclei (*see* LABIO-GLOSSO-LARYNGEAL PARALYSIS). Paralysis may, however, result from meningeal disease outside the medulla, from disease of the bones of the base of the skull, but scarcely ever from disease outside the skull. It occasionally forms part of diphtheritic paralysis.

SYMPTOMS.—The chief symptom is difficulty in

swallowing. Food lodges in the pharynx about the epiglottis, and small particles and liquids may enter the larynx. If the paralysis is limited to the superior constrictor, liquids may, it is said, be forced up into the nose by the contraction of the middle constrictor; but it is doubtful whether this occurs unless the palate also is paralysed. The affection of one nerve causes only slight trouble in deglutition, no doubt because of the circular arrangement of the muscular fibres.

DIAGNOSIS.—The only conditions with which paralysis of the pharynx can be confounded are spasm and organic disease. The writer once saw an elderly man with distinct pharyngeal paralysis, who had been sent to an eminent surgeon because the difficulty in swallowing was supposed to indicate cancer of the throat. A careful examination is usually sufficient for the distinction.

(2) Spasm.—Spasm of the pharynx may be recognised by its paroxysmal character, and is almost always part of 'functional' nervous disease. It forms part of the spasm of hydrophobia, and occurs in hysteria, and in some other allied states. Individuals are sometimes met with who are unable to take food except when alone, so great is the amount of pharyngeal spasm which results from the emotion induced by the presence of other people. Other emotional states may have a like effect; in fear and intense grief swallowing may be impossible partly from this cause.

2. Laryngeal Branches.—It will be remembered that, of the two laryngeal nerves, the superior is the sensory nerve for the larynx, and also supplies motor power to the crico-thyroid muscle, which is the tensor of the cords; while the recurrent laryngeal is purely motor, and supplies the other muscles. The motor fibres of both are derived from the spinal accessory. Of the muscles, the most important in regard to paralysis are the chief abductor, the posterior crico-arytænoideus (which draws the postero-external angle of the arytenoid cartilage backwards, and so moves the processus vocalis outwards); the chief adductor, the lateral crico-arytænoideus (which draws the postero-external angle of the arytenoid cartilage outwards, and thus the processus vocalis inwards); and the arytenoideus (which approximates the two arytenoid cartilages). Other muscles, acting at the same time, increase the power of closure. The paralyzes and spasm of the larynx are described in a separate article. *See* LARYNX, Diseases of.

3. Pulmonary Branches.—The muscular fibres of the bronchi are innervated by the nerve, and their paroxysmal contraction in asthma is believed to be produced through its agency. It has been asserted that the plain muscular fibres, said to exist throughout the lung-tissue, are supplied by it (Gerlach), and their contraction has been assumed to explain a peculiar form of emphysema, which has been observed in compression of the pneumogastric (Tuczek); but, since deep breathing of a costo-superior type was observed, it is possible that the effect is the result of the energetic respiration from the disturbance of the centre. The pneumogastric is commonly believed to contain vaso-motor fibres for the vessels of the lungs, but Brown-Séquard and Franck have separately shown that these fibres are contained, not in the vagus, but in the sympathetic. Vascular lesions of the lungs have, however, been observed after section of

the vagus. Michaelson noted rapid congestion and hæmorrhage, and such congestion is sometimes noted after lesions of the pons. In a case of hæmorrhage into the pons, fatal in two hours, the writer found intense congestion with extravasation into the left lung, and hæmorrhages in the left extremity of the stomach.

After section of the vagus, animals die from chronic pneumonia, and hence the vagus has been supposed to be a trophic nerve for the lungs. But the changes have been accounted for by the entrance into the bronchi of food from the pharynx, in consequence of the obstructive paralysis of the œsophagus, and the paralysis of the larynx (Traube, Steiner). All admit that this is one cause of the pulmonary affection, but differ as to its adequacy.

4. Cardiac Branches.—The inhibitory effect of irritation, and the acceleration of the heart's action which results from lessened action of the vagus, have been before alluded to. Increased frequency has been several times observed in cases of local disease of the vagus in the thorax, compression by mediastinal tumours, &c. In a case of phthisis, for instance, in which the pulse was at first occasionally, and afterwards constantly, frequent (130-148), Meixner found the left vagus enclosed in a mass of enlarged glands in the upper opening of the thorax. The vagus is also the afferent nerve from the heart, and although we are normally unconscious of the cardiac action, some of the disordered sensations of disease are apparently produced through its agency. The subject of angina pectoris, and its relation to the vagus, is discussed in a separate article, but it may be here noted that in some anginal attacks the heart's action is, for a time, arrested or retarded, and that in a few cases these symptoms have been found associated with organic disease of the cardiac plexus. Thus in a case in which, during paroxysms of intense anginal anguish, the heart's action was arrested for four or six pulsations, Heine found a tumour involving the cardiac plexus. In a case recorded by Blandin, anginal attacks were associated with a small tumour of the vagus. Further, there are afferent fibres from the heart inhibiting the action of the vaso-motor centre, and these are probably stimulated in some anginal seizures. See *ANGINA PECTORIS*.

After disease or injury of the vagus, the heart has been found in a state of fatty degeneration, and hence it has been thought that the vagus contains trophic fibres for the cardiac substance.

5. Branches to the Alimentary Canal. The branches to the œsophagus are rarely diseased except in cases of affection of the nerve-trunk or of the centre. In very rare cases such disease has caused difficulty in swallowing, simulating stricture. Spasm of the œsophagus is more frequent. The vagus is the sensory, and in part the motor nerve for the stomach. Its fibres are very sensitive to any local irritation, and not rarely the seat of spontaneous neuralgia. Hunger is generally believed to be a pneumogastric sensation, and complete loss of the sensations of hunger and thirst was noted in a case of softening of the root of the vagus from an aneurysm of the vertebral artery (Johnson). Appetite, however, is not always lost in animals when the pneumogastriacs have been divided (Reid). In some cases of disease of the nerve, excessive hunger has been noted. This symptom, for instance, was present, in one case, in conjunction with dyspnœa,

noisy breathing, and vomiting of unaltered food; *post mortem*, both pneumogastriacs were found atrophied (Swan). In another case of insatiable appetite, small neuromata were found on the nerve. It is possible that the polyphagia may be in part the result of the defective digestion of food.

The pneumogastric is also in part the motor nerve of the stomach; after its section the contractions of the organ are lessened, although not altogether arrested. Vomiting is probably produced through its agency, by varied reflex and central irritation. In the latter case (as in meningitis) the vomiting is sometimes extremely rapid. The writer has known paroxysmal vomiting to result from the intermitting pressure of a tumour on the vagus; and Boinet, having exposed the vagus in an operation in the neck, noted that whenever he touched the nerve the patient vomited.

The vagus accelerates the contraction of the intestines, but no intestinal symptoms have been observed to result from its disease.

GENERAL DIAGNOSIS.—The chief symptoms on which the diagnosis of disease of the vagus, in any given case, would rest, are the laryngeal paralysis; retarded respiration; accelerated or retarded heart; and vomiting. The diagnosis of the seat of the disease rests upon the range of the symptoms, and the associated morbid processes. Disease of the trunk of the vagus is much less common than disease of its branches or roots. Paralysis of one vocal cord, for instance, is almost always the result of pressure, either on the recurrent laryngeal nerve, or on the roots of the spinal accessory at the medulla. Bilateral symptoms are usually due to central disease, or else (if slight) are of merely local origin. In most cases of pressure on the trunk and branches of the vagus the cause of the symptoms is distinct, the only exception being deep-seated tumours in the thorax.

PROGNOSIS.—The prognosis is that of the cause of the disease, and is sufficiently discussed in other articles.

TREATMENT.—Little can be said on the general treatment of the diseases of the pneumogastric, since it depends on the different conditions to which the symptoms are due, and which are described elsewhere. Central disease, and causes of pressure on the nerve, are, as a rule, beyond the range of treatment. Whenever there is reason to suspect pressure on the nerve-roots (from the combination of paralysis of the tongue, palate, and one vocal cord), iodide of potassium should be given, since this condition is more frequently due to syphilis than to any other cause. In laryngeal paralysis the local application of electricity is sometimes useful, but more so in the weakness which depends on local causes than in that which is due to nerve-lesions. Injections of strychnine are of especial importance in degenerative diseases, even when its administration by the mouth is without effect. In central paralysis the treatment will depend on the indications given by the mode of onset regarding the nature of the lesion, whether acute softening or degeneration. In all spasmodic affections, sedative inhalations, as chloroform, are useful; and of especial service is the diminution of the afferent impressions from the larynx such as may be produced by the application of cocaine. Bromide of potassium and morphine alone lessen, in effective degree, the irritability of the nerve-centre.

W. R. GOWERS

PNEUMOGRAPH (πνεύμων, the lungs; and γράφω, I write).—An instrument for recording the movements of respiration. See PHYSICAL EXAMINATION.

PNEUMONIA (πνεύμων, the lungs). Inflammation of the substance of the lungs. See LUNGS, Inflammation of.

PNEUMO-PERICARDIUM (πνεύμα, air; and περιкарδιον, the pericardium).—A collection of gas in the pericardium. See PERICARDIUM, Diseases of.

PNEUMOTHORAX (πνεύμα, air; and θώραξ, the chest).—A collection of gas in the cavity of the pleura. See PLEURA, Diseases of; and LUNGS, Perforation of.

POCK.—A popular term for pustule, as though a pocket or pouch in the skin filled with pus. From the plural of pock is derived *pox*; hence, *small-pox*, *chicken-pox*, the *great pox* or *venereal pox*, and so forth.

PODAGRA (πούς, the foot; and ἄγρα, a seizure). A common synonym for gout, as it usually attacks the foot. See GOUT.

PODALGIA (πούς, the foot; and ἄλγος, pain).—A name for pain in the foot, due to any cause, such as gout, rheumatism, &c.

POISONOUS ANIMALS.—See VENOM AND ITS EFFECTS; VENOMOUS ANIMALS.

POISONOUS FOOD.—See FOOD, POISONOUS.

POISONOUS GASES.—See CARBONIC ACID, Poisoning by; CARBONIC OXIDE, Poisoning by; PRUSSIC ACID, Poisoning by; &c.

POISONS.—SYNON.: Fr. *Poisons*; Ger. *Gifte*. DEFINITION.—There is no legal definition of the word *poison*, and the definitions usually proposed are apt to include either too much or too little. Generally a poison may be defined as a substance having an inherent deleterious property, which renders it capable of destroying life by whatever avenue it is taken into the system. Substances which act only mechanically, such as powdered glass, are not poisons. In popular language, a poison is a substance capable of destroying life when taken in small quantities. A poison, then, may be defined as any substance which, when introduced into the system, or applied externally, injures health or destroys life irrespective of mechanical means or direct thermal changes. See FOOD, POISONOUS.

ACTION.—Poisons may exert a twofold action. Their action is either local or remote, or both local and remote. The local action of a poison is usually one of corrosion, inflammation, or an effect on the nerves of sensation or of motion. The remote actions are usually of a specific character, though some writers group the remote effects of poisons under two heads, and speak of the common and specific remote effects of a poison. The local actions of a poison of the corrosive class are usually so well marked, and so easily recognised, that the fact of its administration is obvious. The same may be said, in a lesser degree, of the irritant poisons, especially the mineral irritants; but here the symptoms often so closely simulate those of natural disease, as to render the diagnosis a matter

of great difficulty. An accurate acquaintance with the remote specific effects of the various common poisons is indispensable to the medical practitioner. The class of poison which has been administered or taken will thus be suggested to his mind by the symptoms observed, and not infrequently the specific poison will be suspected. In this way the physician may often be at once able to diagnose, from the symptoms alone, the administration of strychnine, belladonna, or cantharides. Great care must be taken, however, not to draw a rash conclusion from one symptom; as, for instance, from the tetanic spasms which are so marked a feature in strychnine-poisoning.

It is now universally held that absorption is necessary in order that a poison should be able to exert its specific effect.

MODIFYING CIRCUMSTANCES.—The usual action of poisons may be greatly modified—(1) by the largeness of the dose, and the state of aggregation, admixture, or chemical combination of the poisons themselves; (2) by the part or membrane to which they are applied; and (3) by the condition of the patient. Thus, for example, opium may be a medicament or a poison, according to the dose in which it is given; and a dose of opium which may be beneficial to an adult, in certain states of the system, may be fatal to a young child, or to the adult when suffering, for example, from Bright's disease. All barium-salts are poisonous, except the sulphate, which is one of the most insoluble of all mineral substances. The simple cyanides are highly poisonous, and the same may be said of many double cyanides. But the double cyanide of iron and potassium (potassium ferro-cyanide) is almost without action on the system. The part or tissue to which a poison is applied must obviously greatly affect the activity of a poison, owing to the varying rapidity with which absorption takes place through the cutaneous, mucous, serous, and other surfaces of the body. Curare may be swallowed in a considerable dose without producing any appreciable effect, while a small quantity of the same substance introduced into a wound will speedily prove fatal. It has been found that when a poison is slowly absorbed, so that it can be either disposed of in the system or again excreted more rapidly than it is absorbed, no poisonous results ensue; but when absorption occurs so quickly that the poison can neither be excreted nor destroyed in the system as rapidly as it is absorbed, the specific effects of the poison are developed. Curare, for instance, is absorbed by the gastric mucous membrane more slowly than it is excreted through the kidneys. But if the renal arteries be ligatured, the poison accumulates in the blood, and the specific effects of the poison are developed, just as when curare is introduced into a wound.

Idiosyncrasy has much to do with the poisonous or hurtful character of a substance. Thus pork, mutton, certain kinds of fish, notably shell-fish, and fungi (see MUSHROOMS, Poisoning by), have, under certain circumstances, and in certain persons, produced all the symptoms of violent irritant poisoning; while others, who have partaken of the same food at the same time, have enjoyed perfect immunity. More commonly, all who partake are affected, but with varying degrees of severity. Some persons are said, on good authority, to be capable of taking with impunity such violent poisons as corrosive sublimate or opium in enormous doses,

and this independently of habit, which is known to have such a large influence in modifying the effects of some poisons, notably of the narcotics. A tolerance of poisons is sometimes engendered by disease, so that a poison may from this cause fail to produce its accustomed effect. Thus opium is largely tolerated in tetanus, and in mania from drink; and mercurial compounds may in severe febrile affections fail to produce the usual constitutional effects of the metal. On the other hand, kidney-disease, by impeding elimination, may intensify the ordinary effects of a poison; and the like is observed when opiates are given where there is a tendency to cerebral congestion.

EVIDENCE.—In order to raise a valid inference in the mind of a medical attendant that poison has been administered to a patient, certain facts must be brought under his notice; and without the concurrence of at least two or more of these, the actuality of poisoning cannot be maintained. The sources of evidence in cases of suspected poisoning are the *symptoms*; the *post-mortem appearances*; *chemical analysis* of articles of food or drink, or of the body and the excretions; and *experiments upon animals*. The evidence derived from these sources, being compared with the known properties and effects of various poisons in authenticated cases, will enable the physician to form a correct opinion as to the probable administration or not of a poison. The poisons most commonly taken or administered are opium and morphine, carbolic acid, arsenic in various forms, phosphorus, oil of vitriol, strychnine, and oxalic acid.

It is rarely that the *symptoms* exhibited during life do not afford some clue to the cause of illness; and most frequently the symptoms are all that the medical attendant has to guide him to a diagnosis of the nature of the case, during the lifetime of the patient. Sometimes, however, persons are found dead as the result of poison, concerning the manner of whose death nothing whatever can be learned; a suspicion of poisoning arising from the circumstances under which the corpse is found. Here the aid of chemical analysis ought invariably to be invoked; and fortunately in these cases the delay involved in making an analysis is of comparatively little moment. The effects may in the case of many persons be either suddenly or slowly manifested; hence we have *acute* and *chronic* poisoning. Cases of chronic poisoning are usually the result of the repeated administration of small doses of lead, copper, mercury, phosphorus, or arsenic. All of these poisons are treated of in separate articles. The general conditions which should excite a suspicion of poisoning are the sudden onset of serious and increasingly alarming symptoms in a person previously in good health, especially if a prominent symptom be epigastric pain; or where there is complete prostration of the vital powers, a cadaverous expression of the countenance, an abundant perspiration, and speedy death. In all such cases the aid of the chemist is required, either to confirm well-founded, or to rebut ill-founded, suspicions.

CLASSIFICATION.—Various attempts have been made to classify poisons rationally. Perhaps the best classification, for the purposes of the medical practitioner, is that which groups poisons according to the more obvious symptoms which they produce. Our knowledge of the more intimate action of many poisons is still too slight to admit of any

useful classification according to the manner in which they specifically affect the vital organs.

Poisons may in the manner indicated be classified as: (1) **Corrosives**; (2) **Irritants**; and (3) **Neurotics**. It is perhaps at present premature to attempt a systematic division of the last class. The class of neurotics embraces poisons so widely different in their action as opium and strychnine.

1. Corrosive Poisons. — ENUMERATION. —

The action of one of the most typical of these poisons, corrosive sublimate, is fully considered under a special head (*see* MERCURY, Diseases arising from). The most commonly administered corrosives are the mineral acids—sulphuric, nitric, and hydrochloric; oxalic acid; the alkalis—potash, soda, and ammonia; acid, alkaline, and corrosive salts—such as acid potassium sulphate, potassium carbonate, chlorides of zinc, tin, and antimony, and silver nitrate.

SYMPTOMS.—The mineral acids and the alkalis have no specific effect on the system, their action being at first almost purely local. Some of the other corrosives enumerated may have, besides their local effects, a remote and constitutional action. The symptoms of corrosive poisoning are marked and unmistakable, except when the patient is an infant. Immediately after swallowing the corrosive substance, an acid, caustic, or metallic, burning sensation is felt in the mouth, fauces, gullet, and stomach; and this speedily extends over the whole abdominal region. Vomiting is speedy, or may, rarely, be altogether absent. The vomited matters consist at first of the ordinary contents of the stomach, more or less altered by the action of the poison. In the case of *mineral acids* they are intensely acid, and cause copious effervescence when they fall upon limestone or marble. No relief is afforded by the evacuation of the stomach; and later the vomited matters may be more or less mingled with altered blood, which may be dark, or even black. Shreddy mucus, casts of the gullet or stomach formed by the shedding of the mucous membrane, and sometimes even the muscular wall of the œsophagus, are ejected. The abdominal pain is not relieved, but greatly aggravated, by pressure. The whole abdomen becomes distended, owing to the gases evolved by the action of the poison; the diaphragm is pressed upon, and intense dyspnoea may result, owing to pressure upon the thoracic viscera. When a mineral acid has been administered, there is little or no action of the bowels, and the urine may be suppressed; but in poisoning by the *alkalis*, and by the *alkaline carbonates and sulphides*, there may be purging. The mouth, tongue, and fauces exhibit the local effects of the corrosive: a yellow coating in the case of nitric acid; white at first, and as if covered with white paint, from sulphuric acid; and whitish or brown and less thickly coated from hydrochloric acid. Yellow or brown stains may be observed on the skin, extending downwards from the angles of the mouth, and caused by the trickling of acid or other corrosive fluid from the mouth. Meantime the symptoms develop rapidly. The pain, thirst, dyspnoea, and dysphagia increase. The patient, at first excited, with rapid bounding pulse, becomes bathed in cold perspiration, the countenance becomes pinched, the pulse more rapid and thready. Enormous eructations of gas take place, but these afford no relief. The patient may become more or less cyanosed; but this will depend

upon the amount of dyspnoea. The intellect is usually clear to the last. Signs of collapse come on, and the patient may sink within a period varying from six to twenty-four hours. If recovery does not take place, death usually supervenes within a period of twelve to twenty-four hours. Very frequently, and more especially in poisoning by oil of vitriol, the patient survives the first acute symptoms only to perish months after, should not the aid of the surgeon be invoked and gastrostomy be performed, by slow starvation, due to local injury to, and subsequent stricture of, the oesophagus. The use of bougies in these cases, to keep the gullet patent, seldom affords permanent relief.

When *nitric acid*, or *ammonia*, is the poison taken, the vapours of the acid or of the ammonia may gain access to the air-passages and lungs, provoking inflammation, which is commonly fatal. The dyspnoea and chest-symptoms will be greatly aggravated in these cases, and may overshadow the more usual symptoms due to local action on the digestive canal. In poisoning by the *caustic alkalis* (potash- and soda-lyes) diarrhoea, with discharge of blood, is more common than the constipation observed in poisoning by the mineral acids. Entire suppression of urine, or anuria, is the rule in poisoning by corrosive sublimate.

Oxalic acid in concentrated solution is undoubtedly a corrosive and irritant poison. Very commonly, however, it kills by its depressing action upon the heart before symptoms of corrosion have become prominent; or the vomiting, pain, and other more immediate symptoms of corrosive poison are associated with a feeble pulse, clammy skin, nervous symptoms, aphonia, and speedy death, even within ten minutes of the administration of the poison. To quote Christison's language: 'If a person, immediately after swallowing a solution of a crystalline salt, which tasted purely and strongly acid, is attacked with burning in the throat, then with burning in the stomach, vomiting, particularly of bloody matter, imperceptible pulse, and excessive languor, and dies in half an hour, or still more in twenty, fifteen, or ten minutes, I do not know any fallacy which can interfere with the conclusion that oxalic acid was the cause of death. No parallel disease begins so abruptly and terminates so soon, and no other crystalline poison has the same effects.' It must be added that binoxalate of potassium, and the soluble oxalates generally, are as poisonous as the acid itself.

ANATOMICAL CHARACTERS.—The distinction between corrosive and irritant poisons is by no means well marked; and indeed corrosive poisons, when diluted, act as irritants. Hence we shall describe the *post-mortem* appearances of corrosive poisoning under the head of Irritant Poisons.

DIAGNOSIS.—The diagnosis of corrosive poisoning rarely admits of difficulty; and in any obscure cases chemical analysis will remove all doubt.

2. Irritant Poisons.—Irritant poisons are of two classes—*metallic irritants*, and *vegetable and animal irritants*, these latter being grouped together. Perhaps none of them, however, act as pure irritants; and the irritant symptoms which they produce are most commonly accompanied by a well-marked effect upon the nervous system also. An irritant is a poison which causes inflammation of the part to which it is applied, usually the alimentary canal. By far the most important of the metallic irritant poisons is arsenic (*see ARSENIC, Poisoning by*).

Other metallic irritants are the salts of antimony, zinc, and other metals. Elaterin, essential oils, and gamboge may be cited as examples of vegetable irritants; and cantharides of animal irritants. Irritant animal and vegetable foods are separately described. *See FOOD, POISONOUS.*

SYMPTOMS.—Irritants differ as a rule from corrosive poisons in the greater slowness with which the symptoms are developed. Usually when an irritant is swallowed, after an interval—greater or less according to the specific character of the poison—a burning pain is felt, and a sense of constriction of the mouth, throat, and gullet, speedily followed by sharp burning pain in the epigastrium; and this is increased by pressure—a mark which serves to distinguish the attack from one of ordinary colic. Nausea, vomiting, and great thirst ensue; speedily followed by pain and sense of distension of the whole abdomen, which is exceedingly tender, and perhaps visibly distended. Most commonly the vomiting is followed by purging, tenesmus, dysenteric stools, and often by dysuria. Should the poison not be speedily removed from the system by vomiting and purging, these continue unrelieved, and increase in severity; and symptoms of inflammatory fever, or it may be of collapse, supervene. The pulse becomes rapid, small, and thready; the countenance is anxious; the skin is bathed in perspiration, now warm, and again cold and clammy. The patient may never rally from the first shock to the nervous system; more rarely, having survived this, he dies in convulsions; or he may perish of inanition after more protracted sufferings. It must be borne in mind that those irritant poisons—such as diluted sulphuric acid—which, when taken in a more concentrated form, act as corrosives, may bring about starvation, necessitating such operative procedure as gastrostomy, by the injury which they inflict upon the oesophagus and stomach. Death after the administration of an irritant poison may, it is obvious, occur at very varying periods after the ingestion of the poison.

DIAGNOSIS.—Irritant poisoning may be mistaken for various forms of natural disease. The diseases with which it is most apt to be confounded are—gastritis; gastric ulcer, with or without perforation; peritonitis; severe colic; sporadic and Asiatic cholera; and rupture of the stomach or intestines. A careful examination of the patient, and the history of the case, will often remove any doubt which may be entertained; but microscopical examination and chemical analysis of the ejecta of the patient will frequently afford the only means of clearing up the case during life. Too frequently irritant poison is not suspected until a *post-mortem* examination is made. In every case where a possibility of irritant poisoning is suggested, the aid of analysis should be invoked. For the diagnostic differences—so far as differences in symptoms are diagnostic—between irritant poisoning and the special diseases above mentioned, the reader is referred to the special articles in this Dictionary.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances in irritant and corrosive poisoning are corrosion of the mouth, fauces, gullet, and stomach, the mucous membrane being shrivelled, altered in consistence and colour, and more or less detached; irritation and inflammation of the stomach and first portion of the small intestines; ulceration; and erosion. In corrosive poisoning the stomach may be perforated, the edges of the aperture being

shreddy; and in the case of sulphuric acid the viscera may be blackened (altered blood) from the action of the acid upon the blood-pigment. The small intestines are implicated to a varying extent, or may altogether escape. The large intestine is often attacked, and this is more especially the case in poisoning by mercurial preparations. Arsenic exerts a specific effect upon the gastric mucous membrane. Remains of irritants may be detected in the intestinal canal, and be recognised by their physical, microscopical, and chemical characters.

3. Neurotic Poisons. — **ENUMERATION.** — Under this head may be ranged a great number of poisons, having this in common, that the symptoms produced by them are more or less prominently associated with the nervous system. The class embraces pure narcotics, such as opium and morphine; chloral hydrate; chloroform; hyoscyamus; digitalis; strychnine; prussic acid; nitro-benzol; phenol (carbolic acid); alcohol; aconite; belladonna, and many others.

SYMPTOMS. — These are necessarily of the most varied character. All that has been already said about the onset of symptoms, their character, and the circumstances under which they have appeared, must be borne in mind in arriving at a diagnosis.

Prussic acid produces its effects in the course of a few minutes; or, it may be, seconds. The course of symptoms is very rapid; and death may be well-nigh instantaneous. The symptoms are convulsions, great disturbance of respiration, with prolonged expiration, dilated pupils, and cyanosis. *See PRUSSIC ACID, Poisoning by.*

Morphine and Opium, after a stage of excitement, produce deep comatose sleep, with slow stertorous breathing; contracted pupils; and clammy perspiring skin; all the other secretions being more or less suppressed. *See OPIUM, Poisoning by.*

Aconite is diagnosed by the peculiar numbness and tingling of the skin which it produces. *See ACONITE, Poisoning by.*

Belladonna, and its alkaloid *Atropine*, widely dilate the pupils, with indistinct vision, and cause intense thirst, mirthful delirium, spectral illusions, flushed face, pyrexia and erythema (p. 421).

Chloroform and *Alcohol* in toxic doses produce profound insensibility; and are, moreover, generally more or less recognisable by circumstances, some of which will be found described under **ALCOHOLISM**.

Nitro-benzol causes symptoms often indistinguishable from those of prussic acid; but in consequence of its insolubility, and the slowness with which the liquid poison is absorbed by the gastro-intestinal mucous membrane, there is often a prolonged interval between the administration of the poison and the onset of alarming symptoms.

Chloral hydrate causes death after a stage of unconsciousness; and there is scarcely any difficulty in ascertaining the nature of the case by the aid of the surroundings of the patient. *See CHLORAL HYDRATE, Poisoning by.*

Carbolic acid or *Phenol* whitens and shrivels the mucous membranes with which it comes in contact, and not only acts as a corrosive, but produces speedy narcosis, and greenish or black urine. The peculiar odour of phenol is always perceptible, though not infrequently overlooked.

DIAGNOSIS. — It is impossible to enter fully into the diagnosis of each individual neurotic poison. The most frequent and important diagnoses have to be made in supposed cases of poisoning by

opium, alcohol, and strychnine respectively (*see p. 338*).

In opium-poisoning the equally contracted pupils; the possibility of rousing the patient by means of external stimuli in all except the later stages—as, for instance, by flicking the feet, the application of the electric current, &c.; and the moist clammy skin, may serve to prevent the case being confounded with one of apoplexy. In alcoholic coma there is great danger of mistaking the nature of the case, in consequence of the frequency with which the alcoholic odour may be met with in cases where alcohol has been taken, either dietetically or medicinally, in moderate or somewhat immoderate doses. The very careful use of the stomach-tube can do no harm, and may not only save the patient if the case be one of alcoholic poisoning, but also serve to clear up the diagnosis. The tetanic spasms of strychnine will have to be differentiated from those of true (traumatic) tetanus. In this there is not usually any insuperable difficulty. Strychnine convulsions are intermittent; do not begin in the lower jaw; are, as a rule, opisthotonic in character, and do not affect the same groups of muscles as are implicated in true tetanus. *See OPIUM, Poisoning by; and STRYCHNINE, Poisoning by.*

TREATMENT. — Only the general principles of the treatment of poisoning can be indicated here. The treatment in poisoning by the most important special poisons is described in separate articles. The question of the use or non-use of the stomach-pump or syphon-tube must be decided by the nature of the poison administered. Where one of the concentrated mineral acids, a caustic alkali, a corrosive salt, oxalic acid in concentrated solution, or carbolic acid, has been swallowed, it is generally held that the stomach-pump should not be used, the danger of perforation of the gullet or stomach being considerable. The soft œsophageal syphon-tube may, however, be nearly always used with safety. In all cases where a non-corrosive poison has been taken, except in the case of prussic acid, where the course of the poisoning is too rapid to permit of the use of the instrument, the application of the tube is advisable and can do no harm; in cases of poisoning by opium and alcohol, the greatest reliance must be placed on evacuation of the stomach by its aid. The corroding acids may be neutralised by the administration of lime-water, or, still better, saccharated lime-water; highly diluted solutions of the caustic alkalis; or, failing these, the continuous use, in frequently repeated doses, of chalk, whiting, or the alkaline carbonates—so as to avoid dangerous distension of the abdomen with carbonic acid gas. On the contrary, the caustic alkalis may be neutralised by the copious imbibition of highly diluted acid liquids. Failing the use of the stomach-tube, or even after the use of this, emetics may be administered, or apomorphine injected. The prompt administration of an emetic is rarely inadmissible. The effects of corrosives and irritants must afterwards be met by appropriate remedies, such as demulcents and oil to sheath the mucous membranes, opiates to relieve pain, &c. The effects of oxalic acid cannot be avoided by the administration of alkalis and alkaline carbonates, for the alkaline oxalates are themselves highly poisonous. Chalk, whiting, and soluble lime-salts precipitate oxalic acid as an insoluble calcium oxalate, and form the best remedies. Soluble sulphates are antidotes for carbolic acid. Oil greatly allays the

intolerable pain attending the local action of this acid. In prussic-acid poisoning artificial respiration, persistently used, is our sheet-anchor, and may be supplemented by galvanism, alternate douches of warm and cold water, and other measures. After the use of the stomach-pump to remove unabsorbed opiates, stimulating liquids containing tannic acid, such as strong black coffee, may be given; and the patient must be kept awake by walking him about, flicking the feet with towels, the application of the faradic current, &c. Atropine in full doses is in some respects antagonistic in its physiological action to opium. Conversely, opiates are regarded as direct antidotes to belladonna. Potassium permanganate destroys morphine. On the same principle of counteracting effects, digitalis and aconite are counter-poisons, and hence antidotes the one to the other. The happiest results have followed the use of full doses of chloral hydrate in strychnine-poisoning; and chloroform may be freely inhaled to allay the tetanic spasms. In alkaloidal poisoning, except where a tetanising poison, such as strychnine or brucine, has been given, the stomach-pump must be employed; and emetics and tannic acid, in the form of tincture of galls, strong black coffee, or strong tea, should also be given, with the object of precipitating the alkaloid as an insoluble tannate. Hypodermic injections of strychnine are invaluable where there is cardiac or respiratory failure.

THOMAS STEVENSON.

POLIO-ENCEPHALITIS.—Inflammation of the cerebral cortex. This is the assumed cause of some cases of infantile hemiplegia, preceded by convulsions and followed by marked rigidity of the paralysed parts. See PARALYSIS, INFANTILE CEREBRAL.

POLYCHROMATOSIS.—A term applied to a condition of the red-corpuscles in which the normal staining-reaction of the hæmoglobin is diminished or lost. See p. 155.

POLYDIPSIA (πολύς, much; and δίψα, thirst).—A synonym for excessive thirst; sometimes used for diabetes. See DIABETES MELLITUS; POLYURIA; and THIRST.

POLYNEURITIS.—See NEURITIS, MULTIPLE.

POLYPHAGIA (πολύς, much; and φάγω, I eat). A synonym for excessive hunger. See APPETITE, Disorders of; and PNEUMOGASTRIC NERVE, Diseases of.

POLYPUS (πολύς, many; and πούς, a foot).—**SYNON.**: Fr. *Polype*; Ger. *Polyp*.

DEFINITION.—This term is generally applied to any simple pedunculated growth, springing from a mucous surface; but it is sometimes extended so as to include malignant pedunculated growths in similar situations.

VARIETIES.—It is clear that no single description will apply to each member of the class. Hence it will be sufficient to enumerate the principal varieties of polypus, a fuller account of most of which will be found in the article TUMOURS, and also in the articles dealing with the diseases of the several organs which they affect.

1. **Polypi of the Nose.**—These are of two varieties—the *mucous* and the *fibrous*; both are classed among the fibromata. Both are covered

with ciliated epithelium. The fibrous variety often involves the structures at the back of the pharynx, forming the so-called *naso-pharyngeal polypus*.

2. **Polypi of the Ear.**—Polypi of the ear resemble polypi of the nose, but present a variety of structure, as some spring from the membrana tympani, others from the interior of the tympanum.

3. **Polypi of the Intestines.**—These polypi are of much more frequent occurrence in the rectum than in any other portion of the intestinal tract. They are composed of tissue resembling that of the mucous membrane of the part, and are described among the adenomata.

4. **Polypi of the Uterus.**—These growths are of three kinds, namely: (a) *cystic*, which are derived from the oviducts of Naboth; (b) *mucous* or *soft*, resembling the polypi of the rectum; (c) *hard* or *fibrous*, consisting of pedunculated fibro-miomata.

5. **Polypi in other situations.**—Less common forms of polypi, consisting of some modification of the mucous membrane from which they are derived, are found in the bladder, the larynx, on the gums, or sometimes in the sinuses communicating with the nose.

TREATMENT.—Though polypi differ somewhat in structure, the treatment of the simple varieties of the class is the same—that is, if removal be considered advisable. Either the pedicle may be grasped and the tumour removed by avulsion; or it may be divided at a stroke by some sharp instrument, or cut through slowly or rapidly by some form of écraseur or ligature.

In removing a malignant polypus the rules to be followed are the same as in the removal of malignant growths elsewhere, see p. 214. See CANCER.

R. J. GODLEE.

POLYSARCIA (πολύς, much; and σάρξ, flesh).—A term for excessive corpulence or obesity. See OBESITY.

POLYURIA (πολύς, much; and οὖρον, urine).—**SYNON.**: Diabetes Insididus; Fr. *Polyurie*; *Diabète Insidide*; Ger. *Zuckerlose Harnruhr*.

DEFINITION.—A malady (or group of maladies) characterised by thirst and a persistently excessive flow of watery urine, which has a low specific gravity and contains neither albumen nor sugar.

Attempts have been made to subdivide this group into smaller sections. One such section is *polydipsia* or *hydruria*, having the characters above specified as those of polyuria; another is *azoturia*, where the solids, especially urea, are in excess of the normal amount; and a third, *anazoturia*, where these are markedly deficient. *Azoturia* has been made to include all cases where urea is unusually abundant, even where the urine is scanty, as in fevers; and will not be discussed in this article. *Anazoturia* very rarely occurs; for, notwithstanding the low specific gravity of the urine in diabetes insipidus, owing to the large amount passed, the quantity of urea may, and often does, exceed that excreted in health. A form of polyuria, often slightly marked, has been described as ‘phosphatic diabetes,’ on account of the excess of phosphates passed. See PHOSPHATURIA.

ETIOLOGY.—Diabetes insipidus is a rare disease. Its incidence is unaffected by conditions of age or sex. It may exist in the new-born infant, and it may be found in the patient of seventy, but on the whole it is a disease of early adult rather than of

advanced life, while it is about twice as frequent in males as in females. Nothing is more marked in connection with the causation of diabetes insipidus than heredity. In a case recorded by Gee, the disease was directly transmitted through four generations. Some members of the family escaped, but some of the children of each of those who escaped were attacked.

Beyond inheritance, nothing very definite can be stated as to the cause and origin of diabetes insipidus. It is often connected with nervous affections or nervous excitement, and sometimes follows upon injuries to the head or disease of the brain. In many cases there is a family history of tuberculosis. Alcoholic excesses, the drinking of large draughts of cold fluids, and sudden exposure to cold, have all been credited with the production of the disease. Beyond these, no valid cause can be assigned; often indeed the disease comes on without even such insufficient reasons as those given above, some of which have doubtless been assigned on the '*post hoc*' principle.

SYMPTOMS.—When diabetes insipidus follows accident or mental emotion, its onset is usually abrupt; in such cases it may disappear with equal suddenness—sometimes as the result of intercurrent febrile disease. During its continuance *unquenchable* thirst (see **THIRST**) and pale watery urine are the two prime symptoms, for there may be little wasting, and the general health may be good. Occasionally there is increased appetite. Usually the bowels are confined and the skin dry. Pruritus and boils, so common in diabetes mellitus, are exceptionally met with in cases of diabetes insipidus, but the skin soon presents an atrophied, dry, withered appearance. Impotence is a well-marked symptom, and amblyopia and troublesome flatulency are not infrequent. The temperature is subnormal, and the arterial tension is not increased. The condition of the patient is tolerable, so long as drink is supplied in plenty, were it not for the disturbed sleep caused by the incessant thirst and the desire to pass water; but any attempt to restrict the quantity of fluid gives rise to intense discomfort. Ultimately this constant strain wears out the patient, and may lead to exhaustion, coma and death, if intercurrent disease do not, in the meantime, supervene.

Of the phenomena of diabetes insipidus the urine alone requires special notice. It is inordinate in its quantity, and of a specific gravity little above that of water. It may remain persistently at 1004 (60° F.); but it may rise to as much as 1008 or 1010. It is transparent, almost like water, of a faint greenish-yellow tint, with little taste or smell, and of faintly acid or neutral reaction. The quantity varies with the amount of water consumed. On the whole, the quantity passed is greater than in diabetes mellitus, and may sometimes be measured by gallons. Urea, though relatively deficient in any specimen of urine examined, has sometimes been found absolutely in excess, sometimes diminished. On the other hand, uric acid seems diminished, but this may depend on the difficulty of estimating it in urine so greatly diluted. Sulphates, chlorides and phosphates, especially the earthy salts of the latter, are usually increased, while the only abnormal constituent, if such it can be called, said to have been occasionally detected is inosite; but the reactions of this substance, which has the same percentage composition as a sugar, but which

belongs to the benzol-series, are very unsatisfactory when occurring in urine. Acetone, diacetic and oxybutyric acids, or other products of abnormal proteid-destruction, are never present.

PATHOLOGY.—As in the case of saccharine diabetes, our insight into the morbid processes concerned in the production of polyuria has been greatly aided by direct experiment. Bernard found that by pricking the floor of the fourth ventricle above the level of the 'sugar puncture' he could produce copious diuresis; and in certain animals injuries to the central lobe of the cerebellum (the vermiform process of human anatomy) are followed by a like result (see **MEDULLA OBLONGATA**, Lesions of). From this part of the nervous system the nervous influence seems propagated to the kidneys, both by the splanchnics and spinal cord, but the exact course of the fibres has not yet been clearly demonstrated. Whether the nerves are merely vaso-motor fibres, section or paralysis of which would produce turgescence of the vessels of the kidneys, or trophic fibres, irritation of which would increase the activity of these organs, is not yet determined; but in all probability paralysis of the vaso-motor fibres is the main factor in the production of the polyuria.

In the definition of diabetes insipidus given above disease of the kidneys was expressly excluded; and, as far as the malady itself is concerned, *post-mortem* examinations reveal nothing abnormal, except increased vascularity of these organs, doubtless due to defective innervation of the renal vaso-motor mechanism. As a consequence of the disease, however, persisting over many years, and giving rise to frequent and severe distension of the bladder, when circumstances may prevent its being emptied with sufficient frequency, thickening of the walls of the bladder, dilatation of the ureters, and sacculation of the kidney have been described; but the accuracy of such observations as the results of simple polyuria is questionable. Undoubtedly the most important lesions which bear on the disease are those which have been found in the brain (p. 192), especially in the neighbourhood of the fourth ventricle. These, besides the injuries already alluded to, comprehend tubercular and other forms of inflammation, tumours of various kinds—gliomatous and syphilitic—together with endarteritis and the results thereof (p. 101).

DIAGNOSIS.—The diagnosis of diabetes insipidus rests on the presence of thirst, and persistent excess of urine, coupled with the absence of grape-sugar and albumen. The condition must be carefully distinguished from mere temporary excess of watery urine. Such an excess may occur where a large quantity of fluid of a diuretic kind has been swallowed, especially when there is little or no cutaneous transpiration. Again, sudden diuresis may occur about the period of early convalescence from fever; after the absorption of serous effusions; after an attack of megrim; or yet again when a hydronephrosis suddenly empties itself. All these are merely temporary and evanescent states. The total absence of grape-sugar distinguishes diabetes insipidus from diabetes mellitus, though the former may pass into the latter. In certain forms of Bright's disease, especially those characterised by contracted kidney, the urine may be excessive and of low specific gravity; but in all of these the presence of albuminuria, urinary casts, hypertrophied left ventricle and increased arterial tension will

allow little room for doubt. Finally, polyuria is not to be confounded with such abnormal discharges of urine as may occur from time to time in hysterical persons. Here the nervous symptoms give a special feature to the malady; nevertheless diabetes insipidus has strongly marked nervous affinities.

PROGNOSIS.—This cannot be called favourable, for, while few actually perish from the uncomplicated disease, still fewer are cured of it, though a good many get well. As a rule it runs a chronic course. The onset of anorexia is suggestive of fatal result.

TREATMENT.—Innumerable energetic therapeutic measures have been resorted to with but slight success. If the disease can be assigned to any definite cause, we must deal with it, rather than with the excessive urination; if not, it must be our endeavour to counterbalance the draining of the tissues and the corresponding waste by a plentiful supply of fluid and a generous nourishing mixed and easily assimilable diet given at definite meal-times. No special injunctions are called for in planning the daily diet, but toxæmia from overloaded bowels must be guarded against. The distressing excessive thirst may be somewhat assuaged by sipping acid drinks, or sucking ice dipped in lemon-juice, but sudden withdrawals of liquid should be avoided. To relieve the kidneys from the unusual stress thrown upon them, diaphoretics have been recommended (*see* p. 385). Great care should be taken that the patient be warmly clothed so as to guard against any risk from cold. Of medicinal remedies, that which was once most lauded is valerian, especially by Trousseau, who gave it in enormous doses. Probably it, like other antispasmodic remedies, would be found of most service in cases allied to hysteria or similar neuroses. The whole range of antispasmodic remedies may in some cases be tried without effect. Opium and its alkaloids, though valuable in diabetes mellitus, are worse than useless in diabetes insipidus, except when specially exhibited for insomnia or nervous symptoms. They diminish the thirst and the urine, but they greatly increase the patient's discomfort. Valerianate of zinc, ergotin, iodide of potassium, belladonna, phenazone, trinitrin, and nitrite of sodium, have been tried with varying success. Tonics, especially strychnine and iron, in combination with arsenic, do good by improving the general health. Tea, coffee, and alcoholic stimulants should be interdicted and salt sparsely partaken of. After every drug has been tried in vain, attention to the constitutional state and resort to bracing inland or seaside air either as a primary remedial agent or as an adjuvant may be followed by almost complete disappearance of the polyuria (p. 310). Suitable doses of bromide of potassium at bedtime may be given to children until restlessness with disturbed sleep has passed away. Finally, the constant electric current (1 to 4 milliampères) has been advocated. This electrical treatment is best carried out by applying the positive pole to the nape of the neck, and the negative pole, properly insulated, to the posterior naso-pharyngeal wall. *See* ELECTRICITY IN MEDICINE.

Symptomatic polyuria calls for the treatment of its primary cause. *See* HYSTERIA.

In the treatment of cases of azoturia, strict attention should be paid to the processes of nutrition and assimilation, and all departures from the standard of health remedied. The chylo-poietic tract should be unloaded by occasional doses of blue

pill or calomel, or by a course of Pil. Hydragr. Subchlor. Co. followed each morning by a mild dose of some aperient water. The patient should have a daily morning bath or a tepid or warm salt-water bath (*see* BATHS, p. 138), followed by systematic friction of the whole body. The general vigour of body should be still further promoted by graduated Swedish exercises. The diet should be simple, and the habits of the patient strictly regulated. An important element in treatment is rest. Complete freedom from mental strain and removal from occupations calculated to foster mental disquietude should be secured. Change of scene and cheerful mental surroundings will therefore be useful adjuncts, and to this end a visit to such bracing air as that of Newquay, Cromer, Margate or Braemar will markedly aid the other therapeutic measures.

JOHN HAROLD.

POMPHOLYX (πομφόλις, a bulla or bladder).—A synonym for pemphigus.

PONS VAROLII, Lesions of.—**SYNON.** : Fr. *Maladies de la Mésocéphale*; Ger. *Krankheiten der Brücke*.

INTRODUCTION.—The pons is liable to a variety of affections, either through morbid processes having their primary seat therein, or by secondary implication from disease originating elsewhere, such as tumours of the cerebellum or base of the skull, aneurysm of the basilar artery, or as an element in chronic degenerative diseases of the central nervous system.

The position of the pons, its close relation to the vital centres of the medulla oblongata, the connection of the sensory and motor paths with the cerebrum and spinal cord on the one hand, and the cerebellum on the other, and the transit through it of many of the cranial nerves, render the symptomatology of pontine affections highly complex.

SUMMARY OF PATHOLOGICAL CONDITIONS.—*Hæmorrhage* into the substance of the pons is by no means uncommon, and may vary from a minute focus up to complete disorganisation and rupture into the fourth ventricle. *Embolism* is not common; but *thrombosis* from *syphilitic* or *atheromatous degeneration* of the basilar artery is frequent, and is the origin of necrotic *softening* of an acute or chronic character.

Hæmorrhage.—Hæmorrhage into the substance of the pons, if of small extent, is not necessarily fatal; but if it be of large amount, death occurs suddenly, or within a very few hours. Sometimes there is a sudden onset of coma, with complete relaxation of the whole muscular system. The pupils are, as a rule, minutely contracted, and the condition resembles profound narcotic poisoning. The temperature may rise to as much as 109° F. or more. Deglutition is difficult or impossible; and death ensues from cardiac and respiratory paralysis, irregularity in the rhythm preceding the fatal issue. At other times, and of great significance from a diagnostic point of view, muscular spasms occur, either general or affecting one side more than the other, with distortion of the face, either from paralysis of one side, or this combined with active spasm of the other.

Tumours may grow in the substance of the pons, but more commonly it is implicated by new-growth originating at the base or in the cerebellum.

Softening.—Acute embolic or thrombotic softening of the pons, with or without loss of consciousness, may lead to death rapidly, with paralytic symptoms; but days may elapse, or even months, after the first onset, with characteristic symptoms indicative of the position of the lesion, and death ensue either from gradual implication of the vital centres, or quite suddenly.

LOCALISING PHENOMENA.—The symptoms most characteristic of lesions of the pons are a combination of paralysis of certain cranial nerves on the one side, and of the limbs on the other. The most common combination is paralysis of the face on the one side, and of the limbs on the opposite, the face being paralysed on the side of the lesion. The facial paralysis in this case resembles peripheral facial paralysis, both in the implication of the orbicularis oculi and degenerative change in the muscles. The limbs may be paralysed as to motion only, or there may be a combination both of sensory and motor paralysis. Sometimes the motor paralysis affects one limb more than the other, and there may be a similar distribution of anæsthesia.

The alternate paralysis of the face on one side, and of the limbs on the opposite, occurs more particularly with lesions situated in the 'crustal' portion of the pons and infra-nuclear in position. If the lesion be higher up, near the *crus cerebri*, the face and limbs may both be paralysed on the side opposite the lesion, and present the characters of ordinary hemiplegia.

Various odd associations of palsies are highly characteristic of pontine disease. Such, for example, are paresis of three limbs, and a bilateral paralysis in which the limbs are affected more on one side than on the other, with or without paralysis of the face on one side.

Next in frequency to affections of the facial nerve, with or without affections of the limbs of the variable character above mentioned, comes paralysis of the abducens or sixth cranial nerve. This gives rise to an internal strabismus, usually of the eye on the same side as the lesion. There may be, therefore, paralysis of the face and abducens on the side of lesion, and of the extremities on the opposite side; but cases have been recorded of paralysis of the abducens on one side, and of the face and limbs on the opposite; and also of paralysis of the face, abducens nerve, and limbs on the same side as the lesion. In some cases there is paralysis of conjugate movement of the eyes towards the side of lesion. This occurs when the nucleus of the sixth, which innervates the external rectus of the same side and the internal of the other, is affected.

The fifth cranial nerve is also not infrequently implicated. The sensory portion seems to suffer more than the motor. But cases have been recorded in which the motor portion of the fifth has been specially affected, leading to paralysis and degeneration of the muscles of mastication.

The paralysis of the sensory division shows itself in more or less marked anæsthesia of the face, which may be general, or limited to the area of distribution of some of the branches. The tongue is not infrequently implicated on the same side, and tactile and gustatory sensibility impaired or abolished over the half of the tongue. The affection of the fifth may occur on the same side as the lesion, with or without affection of the limbs,

but it would appear also that anæsthesia of the face may occur, with implication of the extremities on the side opposite the lesion.

Lesions of a bilateral or multiple character, chiefly in the form of small hæmorrhages or softening, give rise to symptoms of a pseudo-bulbar type; such are weakness of the limbs on both sides, and paresis of articulation and deglutition from interference with the movements of the lips, tongue, and soft palate.

There is thus an extraordinary complexity and variability in the symptoms which may be met with in connection with pontine lesions. Those which have been mentioned are the most common and most significant, especially if they occur in combination. Singly they have less value, and some of them, particularly defects in articulation, are not specially characteristic. But a combination of paralysis of the limbs on one side, either motor alone, or of motility and sensibility, and of the face on the other, is significant of pontine lesion. The addition of paralysis of the abducens adds to the certainty.

The localising phenomena of pontine lesions may be summarised in the following way. The characteristic 'alternate' paralyses are:—

1. Paralysis of the conjugate movement of the eyeballs to one side with palsy of the opposite limbs.
2. Peripheral facial paralysis on one side and paralysis of the limbs on the other.
3. Paralysis of the conjugate movement and of the face on one side and of the limbs on the other.
4. Paralysis of the fifth nerve, motor, sensory or both, on one side, and of the face (cerebral type) and the limbs on the opposite side.
5. Paralysis of one or more cranial nerves on one side, with palsy of motion or sensation or both on the other side.

Many other symptoms might be mentioned which have been noted in connection with lesions of the pons, especially tumours, which ought perhaps to be ascribed to interference with the functions of neighbouring structures. Along with one or more of the previously mentioned symptoms, impairment of deglutition has been observed, due without doubt to pressure on the medulla oblongata. To the same cause should also be ascribed the irregularity and ultimate paralysis of the cardiac and respiratory movements, in connection either with tumours or with hæmorrhagic effusions into the pons itself.

When a tumour presses forward in the direction of the *crura cerebri*, the third cranial nerves may be implicated. Ptosis has been observed in such cases; and external strabismus, from paralysis of the internal rectus, has also occurred, but comparatively rarely.

Vertigo and disorders of equilibrium have been observed, but these may be attributed to an implication of the cerebellum or of its peduncles. Ataxic symptoms have, however, been described as occurring in pontine lesions, without affection either of the cerebellum or of its peduncles. If ataxy is a prominent symptom, disturbances of cutaneous sensibility and of the muscular sense usually co-exist. But the cases which have been recorded are not yet sufficient to establish any very definite propositions in regard to the exact causation or special characteristics of the ataxic disorders in question. In connection with tumours pressing on the pons, hearing

may also be impaired or abolished in one or both ears. Impairment of smell has been observed on one side, when there has been anaesthesia of the face. This is probably due to the impairment of common sensibility in the nostril, intensified in some cases by the defective power of sniffing if the facial nerve is also paralysed.

Albuminuria and glycosuria have occasionally been found in connection with diseases of the pons. It is very doubtful if any causal relationship has been at all satisfactorily established. Very often, when albumen has been found, there is good reason to believe that it has been pre-existing, for lesions of the pons frequently occur in connection with chronic renal disease. Sugar has been found sometimes, and in other cases not. The same has been found in connection with lesions of other nerve-centres.

Diseases which encroach on the intracranial space produce the general symptoms of intracranial tumour, in addition to the special symptoms indicative of their invasion of the pons.

D. FERRIER.

W. A. TURNER.

PORENCEPHALY (πόρος, hole; and ἐγκέφαλος, brain).—A congenital condition in which a number of clefts or depressions extend from the surface of the cerebral cortex into the interior.

POROKERATOSIS.—A thickening and hardening of the epidermis around the orifices of the hair-follicles and sweat-ducts.

PORRETTA (La), in Italy, between Bologna and Pistoja.—Thermal, sulphurous, muriated saline waters. See MINERAL WATERS.

PORTAL OBSTRUCTION.—Strictly speaking, portal obstruction implies that there is some direct impediment to the flow of blood in the portal circulation itself, either affecting the trunk of the vein before it enters the liver, or its branches distributed throughout the substance of this organ. It must be remembered, however, that any condition interfering with the circulation beyond the portal system, whether in the hepatic veins, the upper end of the inferior vena cava, right side of the heart, or lungs, will retard more or less the flow of blood through this system; and also that either of the tributary branches of the portal vein may be affected alone. The portal trunk may be obstructed by direct pressure upon it, as by enlarged glands, a growth projecting from the liver, thickening from perihepatitis, or a neighbouring tumour, or aneurysm; by changes in its walls, leading to constriction or complete closure; or by blocking-up of its channel, as by a thrombus (see PORTAL THROMBOSIS). Cirrhosis of the liver is the most important disease which obstructs the portal circulation within the liver.

EFFECTS.—The effects of portal obstruction will depend on its seat, its degree, and the rapidity with which it is set up. They are merely those which necessarily follow mechanical venous congestion, namely, distension of the small vessels, which may end in changes in their walls and varicosity; escape of serum; a congested or catarrhal condition of mucous surfaces; hæmorrhages; and, in course of time, permanent changes in organs and structures which are thus affected. Their localisa-

tion in this case will correspond with the structures from which the portal vein receives its tributary branches, or with which the latter communicate. Hence any of the following conditions may result in various degrees from portal obstruction: (1) Congestion and catarrh of the mucous membrane lining the lower end of the œsophagus, stomach, and intestines, with consequent disorder of the secretions; dilatation, varicosity, ulceration and rupture of the small vessels; hæmorrhage into other parts of the alimentary canal, especially at the lower end of the œsophagus. (2) Ascites, one of the most frequent and evident phenomena (see ASCITES). (3) Enlargement of the spleen, either from mere accumulation of blood, or in chronic cases with permanent increase and alteration in the splenic structure. (4) Congestion, followed by fibroid changes, in the pancreas. (5) Hæmorrhoids, it is generally believed. (6) After a while, enlargement of the superficial veins of the abdominal wall, owing to their communications with the portal vein; as well as of the veins within the abdomen, which are tributary to it. In rare instances peritoneal hæmorrhage has occurred from the rupture of distended veins. (7) Congestion of the female generative organs in some cases.

Several of the conditions mentioned are obvious on clinical examination during life; others are only evident on *post-mortem* examination, although they assist in originating symptoms, especially in connection with the alimentary canal, such as those of dyspepsia, flatulence, and disordered bowels, diarrhoea being not uncommon. Hæmorrhage into the alimentary tract is usually revealed by the occurrence of hæmatemesis or melæna, but it may prove fatal without any discharge of blood externally. It must necessarily happen that, if the portal circulation is not properly carried on, the functions of the liver are proportionately impaired.

The signs of portal obstruction may set in with great acuteness, or more or less gradually. Those indicative of acute obstruction are the rapid development of abundant ascites, returning speedily after paracentesis; acute enlargement of the spleen; hæmorrhage into the alimentary canal; and speedy dilatation of the superficial abdominal veins. It must be remarked that the most striking phenomena may disappear in chronic cases, after a time, without the removal of the obstruction, probably owing to the establishment of efficient anastomoses, by which the blood is returned to the heart without passing through the liver. These comprise (1) the gastric and œsophageal veins, (2) the mesenteric and inferior hæmorrhoidal, (3) the coronary and phrenic, (4) the veins of Retzius, connecting the intestine and mesentery with the vena cava, (5) the vessels in the suspensory ligament and in any extensive adhesions that may have been formed. See HÆMORRHAGE, p. 620.

DIAGNOSIS.—There ought to be no difficulty in recognising the signs of portal obstruction in marked cases; and it might even be suspected before these signs are well-developed under certain conditions. The cause of the obstruction can only be made out by a consideration of each case in all its features.

TREATMENT.—Rarely can anything be done directly to remove portal obstruction. The portal circulation may often be relieved by acting freely upon the bowels, especially by means of saline and hydragogue purgatives. The special treatment of

the causal conditions upon which portal obstruction depends is described in the articles on those subjects (*see p. 107*). FREDERICK T. ROBERTS.

PORTAL THROMBOSIS.—**SYNON.** : Portal Phlebitis; Pylephlebitis; Fr. *Pyléphlébite*; Ger. *Pylephlebitis*.

Portal Thrombosis may be divided into two kinds: (A) Non-Infective; and (B) Infective.

(A) **Non-Infective Portal Thrombosis.**

CAUSES.—1. *Weakened force of Circulation.*—Thrombosis from this cause—the result of feeble action of the heart, or of marasmus—is a rare occurrence in the portal vein as compared with other veins.

2. *Diseases of the Liver*, causing destruction or constriction of the capillaries of the liver or branches of the portal vein, are the commonest causes. Of this group of causes the most common are:—

(a) *Cirrhosis of the Liver*, the thrombus arising in the smaller branches and then extending to the trunk and main branches; usually firm and hard, partly organised, and adherent to the vessel-wall; the vein itself dilated, and its wall thickened.

(b) *Cancer of the Liver.*—The thrombosis in this case is usually limited to individual branches, which are compressed by the growth. In some cases the thrombus is made up in great part of the new-growth itself. This is specially common with primary cancer of the liver.

(c) *Compression of the Vein* outside the liver by adhesions, the result of chronic peritonitis; or still more frequently by morbid growths of stomach, pancreas, omentum, or retroperitoneal glands. In very rare cases thrombosis of numerous peripheral branches of the portal vein, as the mesenteric veins, has been found giving rise to symptoms very similar to those caused by thrombosis of the trunk of the vein.

SYMPTOMS.—The symptoms of portal thrombosis are those of intense portal obstruction. There is ascites, rapidly developing, and, according to Frerichs, returning rapidly after removal by tapping. The veins of the walls of the belly become rapidly dilated. There may be hæmatemesis or a bloody diarrhoea. The spleen is greatly enlarged. Jaundice may or may not be present.

DIAGNOSIS.—The diagnosis of portal thrombosis is a matter of great difficulty, the symptoms being very like those of cirrhosis, of which, indeed, it is often a mere complication. In general, it is only when the thrombosis is very acute and, affecting the trunk or most of the branches of the vein, and causing very rapid ascites, splenic tumour, dilatation of the superficial abdominal veins, &c., that a diagnosis can be made.

PROGNOSIS AND TREATMENT.—The prognosis is always bad. Instances of recovery are extremely rare; in these cases the vein has been found converted into a fibrous thread, and a collateral circulation established. The treatment must be the same as for cirrhosis in most cases. In the very acute cases, leeches over the liver, cupping, and the administration of saline purgatives should be tried.

(B) **Infective Portal Thrombosis.**—*Pylephlebitis Purulenta.*—Suppurative portal thrombosis is commonly met with in connection with some infective process, in the parts from which the branches of the portal vein arise. Thus infective diseases of the intestines, especially of the vermi-

form appendix (appendicitis) are the most frequent causes. It occurs after dysentery, and more rarely after enteric fever. It is occasionally caused by ulcer and cancer of the stomach, and follows suppurative splenitis. In the newly born, suppuration sometimes extends from the umbilical vein to the liver. The vein is found greatly dilated, and filled with a dirty grey or reddish thrombus, containing organisms. The liver itself shows, on section, the branches of the portal vein filled with a diffuent thrombus and numerous pyæmic abscesses scattered throughout its substance.

SYMPTOMS.—The symptoms closely resemble those of abscess of the liver or of pyæmia. Traube thinks the diagnosis may be made if the liver and spleen be much enlarged, and if there be returning attacks of rigors with raised temperature, while between the attacks the temperature is natural or only slightly raised. Remittent pyrexia, with sweating, vomiting, diarrhoea, and rigors, are the most constant symptoms. The liver, however, is only moderately enlarged in some cases. Pain and tenderness in the right hypochondrium, with an icteric tint, in a case presenting pyæmic symptoms, should suggest this condition. There must be also evidence of some suppuration, which may involve the branches of the portal vein; and pyæmia and endocarditis must be excluded. Often, however, all these signs fail, and suppuration of most of the branches of the portal vein has been found after death when no hepatic symptoms have been present during life. Possibly the occurrence of hepatic symptoms depends upon the acuteness of the process.

PROGNOSIS AND TREATMENT.—The prognosis is always bad; the treatment must be the same as for abscess of the liver or pyæmia.

In view of the frequency with which it is caused by disease of the appendix, any suspicion of pylephlebitis should lead to the careful consideration of the propriety of surgical exploration of the appendix.

POSTURE.—In this article it is intended to point out the main practical relations of posture to the ætiology, diagnosis, and treatment of various diseases.

1. **Ætiology of Posture.**—As an immediate cause of disease, posture is chiefly important in connection with occupation. The evil effects of prolonged *standing* are evidenced by the development of varicose veins in the legs, and also by the occurrence of general fatigue and debility, displacements of the uterus, and other conditions, especially in young women, such as those employed in drapers' shops. Those callings which entail constant or frequent *bending forward* of the body are often very injurious, and this may be aggravated by carrying burdens on the back and shoulders. Not uncommonly persons injure themselves by

habitually bending forward when sitting, quite apart from occupation. Another illustration of the influence of posture in causing disease is where individuals have to work in *constrained positions*, such as colliers and miners. The conditions thus induced are chiefly deformities of the chest, and certain diseases of the lungs, heart, and vessels. A peculiar posture in performing certain acts, such as writing, may have some influence in originating affections of the type of writer's cramp. The *recumbent* posture in low febrile and other conditions aids in the causation of hypostatic congestion and its consequences; a similar position promotes the accumulation of morbid products in the smaller bronchi or air-vesicles, in cases of severe acute bronchitis, which may cause further mischief; and if an attack of pleurisy should supervene when a patient is obliged to lie on his back, this will materially modify the way in which the fluid accumulates, for it tends then to collect posteriorly, and may cover the whole area of the chest in this aspect, while there is no sign of any fluid in front.

2. Posture in Diagnosis.—In many cases the posture suggests great debility, helplessness, or prostration, thus affording important indications as to the general condition of a patient. Patients instinctively assume the position which relieves pain, and which enables them to use sound organs to the greatest advantage. An inability to lie down (*orthopnea*) constitutes a prominent feature in certain forms of cardiac and pulmonary disease, in consequence of interference with the respiratory and cardiac functions, so that the patient is obliged to sit or to be propped up in bed, or sometimes even to sit up in a chair, to assume the erect posture, or to bend forward. Again, when anything is pressing upon the main air-tube—such as an aneurysm—causing obstructive dyspnoea, the patient may instinctively lean forward, so as to take off the pressure as much as possible. In cases of unilateral lung-disease or pleurisy, the patient is often unable to lie on one or other side, especially the affected one; while in affections of the heart it is frequently impossible for him to rest on the left side. As regards abdominal diseases, acute peritonitis is often characterised by a very striking posture, the patient lying on his back, with the knees well drawn up and bent, in order to relax the abdominal muscles. In appendicitis the right thigh alone may be similarly flexed. In spasmodic painful attacks connected with the abdomen, it is very common to see the patient bending forwards in a doubled-up position, and pressing upon the abdomen. In nervous diseases posture may be of conspicuous value in diagnosis. Thus, it may reveal paralysis of different parts; in cerebral meningitis the patient often lies in a curled-up position, all the limbs being bent towards the body; in spinal meningitis the head may be involuntarily drawn backwards, in order to try to relax the muscles behind; in tetanus the body is during the spasm fixed in different positions, according to the muscles affected; in cataleptic conditions any posture that is assumed is retained for a considerable or an unlimited time; while in wry-neck the head is turned to one side. Lastly, the position voluntarily assumed by a limb may give important information as to local diseases or injuries likely to influence it in this respect, such as those of the joints. The whole body may be distorted, as well as

the limbs, in connection with diseases of the articulations.

Change of posture is a useful aid to physical examination. It may give valuable help in determining the presence of fluid in cavities, such as the pleura or peritoneum; in distinguishing an internal aneurysm from conditions simulating this lesion; in detecting certain solid formations in the abdominal cavity; and for other purposes. Details on these points are given in appropriate articles in this Dictionary. It is also of importance to study the position of the patient in examining the chest; and to remember that posture materially influences the position of the heart.

3. Posture in Treatment.—Many of the preceding remarks will afford suggestions as to the value of paying attention to posture as a therapeutic measure, and it will at once be evident that if a wrong posture is the cause of any morbid condition, the first principle in treatment should be to rectify it. Besides, it will not uncommonly be found advantageous to watch patients, and to allow them to adopt, or assist them in adopting, such a position as their own sensations dictate to be the most suitable for their condition. In order to illustrate further, however, the benefits to be derived from posture, it may be well to point out some of the diseases in which its value is most strikingly exhibited.

(a) Posture is of great importance when general rest of the body is required, or when there is exhaustion or prostration of the whole system. The recumbent posture is clearly indicated under these circumstances, for it is the most restful of all, and involves little or no expenditure of muscular force. Hence, in acute febrile diseases of all kinds, one of the first indications in treatment is to keep the patient absolutely in bed. This is also desirable where there is excessive fatigue or prostration from any cause. The great importance of rest in bed during and after an attack of influenza may be specially noted.

(b) In the management of affections connected with the respiratory organs, attention to posture is frequently of service. Here its influence as regards rest again comes in, for it may be of much consequence to make as little call as possible upon the respiratory functions. Moreover, symptoms associated with the breathing apparatus are in many cases strikingly influenced by posture, such as pain, dyspnoea, or cough (*see* RESUSCITATION; and STERTOR); and the act of coughing may be materially assisted, and made more effectual as regards expectoration, by the patient assuming a sitting or erect position. The importance of the prone posture, or of bending forwards, must be remembered when there is anything pressing on the main air-tube.

(c) Posture often requires particular consideration in relation to disorders of the cardiac action, or to actual disease of the heart. Thus, in the syncope state the patient should be placed horizontally, or even with the head at a lower level than the body, so that the blood may more readily reach the brain, and in this way life may be sustained. Bending the head downwards between the knees may prevent threatened syncope. In this state, or when the heart is acting with extreme feebleness from any cause, raising the patient into a sitting posture has been known to cause a fatal result, and should be carefully avoided. On the other hand, there are

conditions of the heart in which the patient cannot possibly lie down, and especially where there is much dilatation; under these circumstances it may be of the greatest service to have him constantly sitting up in a properly constructed chair, and the beneficial effects thus produced are sometimes almost marvellous.

(d) In the treatment of aneurysms, whether internal or external, posture is frequently made use of with advantage. In the cure of this lesion in the chest or abdomen, rest is often an important agent, and on this account patients are confined to the recumbent posture for weeks or months, so as to keep the heart as quiet as possible, and also to limit the demand of the system for food, which is only given in a restricted quantity. Aneurysm in the chest is one of the causes which may originate pressure on the air-tube, and on this account attention to posture may be required in connection with it. In the case of aneurysm in the limbs, posture is sometimes made use of to cure them, by causing pressure, as flexion of the knee for the cure of popliteal aneurysm.

(e) The influence of posture with respect to gravitation may often be recognised with advantage in the treatment of certain conditions. This is well exemplified by its effects on dropsical accumulations in the legs and scrotum. Even abundant anasarca may frequently be got rid of completely in a short time by keeping the legs in a horizontal position; and oedema of the scrotum likewise may soon disappear when this part is propped up. The same principle is of essential importance in checking hæmorrhage from a ruptured varicose vein in the leg; and may also be made use of in the treatment of varicose veins. The influence of posture upon dropsy may give useful information as to its cause, and as to the exact conditions upon which it depends.

(f) As miscellaneous illustrations of the employment of posture in treatment may be mentioned the value of the recumbent position in sea-sickness, in attacks of giddiness, megrim, and neuralgic affections about the head; raising the head in comatose conditions; the prone posture in the treatment of certain forms of spinal disease; prolonged decubency or peculiar positions to restore a displaced uterus; and various positions in which limbs are placed on account of local diseases, to relieve pain, to prevent muscular tension, to promote the escape of pus, or for other purposes.

(g) Lastly, it must be remembered that it is not uncommonly requisite to change the position of a patient more or less frequently, if he should be confined to his bed. For instance, this is necessary in low febrile diseases, in order to prevent the occurrence of hypostasis at the bases of the lungs, or the formation of bed-sores on parts subjected to pressure; as well as in many cases of spinal or cerebral disease, and in very emaciated patients. Change of posture is further useful in assisting the escape or expulsion of morbid secretions from the air-passages, when they tend to accumulate there.

POULTICE (πόλτος, porridge; *puls*, thick soup).—SYNON. : Cataplasm; Fr. *Cataplasme*; Ger. *Breiumschlag*.—Poultices are soft moist applications, usually applied hot, but occasionally cold. They may be used merely as a means of applying heat and moisture; or they may contain some drug intended to exert a specific effect. They are now largely replaced by fomentations. There are only two poultices in common use, (1) the *simple* poultice, composed of crushed linseed, and (2) the *counter-irritant* poultice, composed generally of crushed linseed and mustard.

1. **Simple Poultice**.—The simple poultice, by its heat, causes a dilatation of the vessels of the part to which it is applied, and thus hastens the progress of inflammation, either towards resolution or suppuration. It softens the cuticle, and relaxes the skin by its moisture, and thus favours swelling, and lessens tension and pain. In internal affections, such as bronchitis, pleurisy, or pericarditis, large poultices are frequently applied to the skin over the inflamed part. They benefit the patient partly by their warmth, and partly by exerting an extremely mild counter-irritant effect (p. 349), consequent upon the redness and congestion of the skin which they produce. They are, however, somewhat troublesome; they soon become cold; and if the patient be restless, their weight causes them to shift, and fragments break off and drop into the bed, and there drying cause considerable discomfort. For application to boils and wounds they are altogether unsuitable. See FOMENTATIONS.

In internal inflammations a poultice may often be advantageously replaced by cotton-wool only, covered with oil-silk and secured by a bandage. If any counter-irritant action is required, a few drops of chloroform or turpentine may be sprinkled on wool or spongio-piline.

Linseed-meal poultices are best prepared with recently crushed linseed (*Linum Contusum*, B.P.), as the meal tends to become rapidly rancid. The following is a useful method of making a linseed-meal poultice: Heat the basin in which the poultice is to be made with boiling water; then empty it and put into it again as much boiling water as may be necessary to make the required poultice; sprinkle the crushed linseed into the water, stirring vigorously, till the proper consistence is attained. By adopting this plan the poultice will be free from lumps. The poultice should then be spread with a broad spatula, previously moistened with water, on a piece of rag or tow. It must be of a uniform thickness, and neither so thick as to be too heavy, nor so thin as to cool and dry too rapidly. A poultice should be changed every two or three hours by day, and every four at night, if the patient is sleeping.

2. **Counter-irritant Poultice**.—*Cataplasma sinapis*, the ordinary mustard poultice, is an invaluable counter-irritant. It is composed of mustard in powder, $2\frac{1}{2}$; crushed linseed, $2\frac{1}{2}$; boiling water, 10. The crushed linseed is to be mixed with the water, and the mustard added, constantly stirring. Its action should extend only to producing redness of the skin, for if kept on too long it will cause vesication, and has even been known to give rise to sloughing. The time a mustard poultice can be kept on varies from ten minutes to half an hour or more, according to the strength of the mustard. The sensations of the patient can usually be relied upon as a guide. An ordinary patient

is not likely to keep it on too long, as the smarting soon becomes unbearable. If the proportion of mustard be reduced to 1 in 4 or 5, the poultice will take an hour or more to produce the desired effect, and, in this form, is a much safer application in the case of young children. Patients who are much in the habit of applying mustard poultices to the same part—as, for instance, the front of the chest—acquire a singular power of resistance to the irritative action of the mustard. The mustard poultice is indicated whenever mild and rapid counter-irritation is desired. It is especially useful in bronchitis, and in muscular rheumatism, as lumbago or pleurodynia. Rigolot's mustard-leaves, and the *charta sinapis* of the *British Pharmacopæia*, are excellent substitutes for the mustard poultice. They are cleaner, more easily applied, and can be more accurately adapted to the spot required. They should always be used in preference when obtainable.

MARCUS BECK.

H. MONTAGUE MURRAY.

PRÆCORDIAL ANXIETY or OPPRESSION.

SYNON. : Fr. *Angoisse* ; Ger. *Præcordialangst*.

DEFINITION.—A sensation of constriction, attended with anxiety, referred to the præcordia ; for the most part persistent, but at times recurrent and depending on dilatation of the heart. See PAIN IN VISCERAL DISEASE, p. 1141 ; ANGINA PECTORIS, p. 66 ; and HEART, Dilatation of, p. 635.

PRÆCORDIAL PAIN.—SYNON. : Heartburn ;

Fr. *Cardialgie* ; Ger. *Magenschmerz*.

DEFINITION.—Pain referred to the region of the heart. Pain in the region of the heart may be due to local causes or may be reflected from the heart or some other viscus associated with the præcordial region of the chest. See PAIN IN VISCERAL DISEASE, p. 1141.

PRÆSYSTOLIC.—A term implying antecedence to the ventricular systole, and used in connection with a cardiac murmur or thrill occurring during this period of the cardiac revolution. See HEART, VALVES AND ORIFICES OF, Diseases of ; and PHYSICAL EXAMINATION.

PREBLAU, in Carinthia, Austria.—Acidulated alkaline waters. See MINERAL WATERS.

PREGNANCY, Disorders and Diseases of.

The most common, and therefore the most important, serious disorder of pregnancy is its premature termination by abortion or miscarriage. This is considered separately under the headings of ABORTION ; PLACENTA, Diseases of the ; and MOLE. In the present article, therefore, abortion will only be considered incidentally in its relation to certain diseased conditions which have an unfavourable influence on the pregnant state and tend to favour its miscarriage.

Under the present heading will be considered :

I. Diseases of pregnancy caused by neuroses, or blood-changes. II. Diseases caused by pressure. III. Diseases caused by misplacement of the pregnancy, or of the uterus containing the pregnancy (under this division *Extra-Uterine Pregnancy* will be considered). IV. Diseases caused by abnormal conditions of the uterus itself (or of the uterine appendages) other than displacement. V. Diseases caused by pelvic deformity or bony outgrowth. VI. Finally, as there are certain medical

and surgical diseases, as well as certain surgical operations, which have been found seriously to affect the normal progress of pregnancy or parturition, these and their influences on the pregnant state will be considered in some detail.

I. Diseases caused by Neuroses or Blood-changes: (1) Vomiting (Hyperemesis) ; (2) Salivation (Ptyalism) ; (3) Unusual appetite ; (4) Dental caries ; (5) Cutaneous disorders ; (6) Chorea gravidarum ; (7) Mental perversion.

1. Vomiting (*Hyperemesis gravidarum*).—The vomiting of early pregnancy is a very common symptom. It is usually (but by no means necessarily) confined to the earlier part of the day, and is generally started by getting out of bed, or by any very marked change of position. It may begin within a week after conception has taken place and persist throughout the whole of pregnancy, but it is during the second, third, and fourth months that the disorder is generally more acute.

In severe cases nearly everything is rejected from the stomach as soon as it is swallowed, and progressive emaciation and weakness may be extreme. When this is the case, it is well to remember that pregnancy may be complicated with graver disease, and that the vomiting may be due, not to one condition only, but to both conditions. In two cases of this kind within the writer's experience, both of which were treated unsuccessfully—one by emptying the uterus, and the other, first by replacement of a gravid retroversion, and afterwards by emptying the uterus—the fatal issue was found to be due to grave complication : in the first case, to malignant disease of an ovary, and in the second to contracting adhesions of the small intestine, due (probably) to old peritonitis in the neighbourhood of a gastric ulcer.

The vomiting of pregnancy is essentially a nervous disorder, but movement of the enlarged uterus, temporary heart-weakness or faintness, and some abnormality of the pregnancy (gravid retroversion, spasmodic closure of the cervix, abnormal placental attachment) may be looked upon as exciting causes, and their consideration as such lead the practitioner to suitable treatment.

TREATMENT.—In minor cases, change of residence, life in the open air, and the administration of a vegetable bitter with dilute mineral acid before food, may be all that is necessary (Acid. Nitro-Hydroch. Dil. m x-xv, Infusi Gentianæ ad zj : t.d.s.). When sudden movement causes nausea, suitable advice should be given regarding this. When the nausea is associated with faintness, a dessertspoonful of brandy may be given once or twice daily, the administration being stopped as soon as the symptom is relieved. When gravid retroversion is found, this, as a rule, should be replaced. When the cervix appears to be specially contracted and sensitive, gentle dilatation may immediately relieve the associated symptom.

In all severe cases, when no intercurrent or associated disease can be made out, the following plan of treatment is recommended. The patient is fed by nutrient enemata, all food by the mouth being temporarily withheld. Twice a day, if necessary, the patient is given an enema containing zj of the mixed bromides (zss Potassium Bromide, zss of Sodium Bromide) and 20 grs. of Chloral Hydrate. This may be administered in zj – zij of beef-tea, and should be entirely retained if possible.

As soon as the bromide and chloral hydrate

begin to affect the system the vomiting lessens, and nourishment may be cautiously given by the mouth. When this is retained by the stomach, the enemata are discontinued and the same drugs given in one-fourth doses, in the form of mixture (R. Chloral Hydrat. grs. iv-v, Potassii Bromidi, Sodii Bromidi aa grs. viiss, Aquam ad ʒj). In cases of less severity this mixture may be employed from the outset.

In all severe cases temporary confinement to bed is a necessity. In some cases this has been apparently continued with advantage throughout the whole of the pregnancy. In other cases dangerous vomiting has been promptly relieved by the induction of abortion. If the method recommended above be thoroughly adopted, these methods of treatment (to which there are grave objections) will rarely, or never, be necessary. *See VOMITING.*

2. *Salivation.*—Salivation is a rare disorder of pregnancy. It is generally associated with nausea and vomiting and sometimes appears to be forced into undue prominence by the refusal of the patient to swallow her saliva. Very similar treatment to that advised for vomiting is most successful. Full doses of the mixed bromides are given persistently, and the patient should be encouraged to dispense with the constant use of the spittoon or handkerchief. In cases where the gums are swollen and the breath offensive, the practitioner should prescribe a mouth-wash of chlorate of potassium (grs. x ad ʒj), and inquire into the possibility of any coincident mercurialism. Atropine, pilocarpine, and galvanisation of the cervical sympathetic have all been tried for the relief of this condition, but on the whole these methods appear to be inferior to the treatment by bromides.

3. *Unusual Appetite.*—The appetite of the pregnant woman may be subject to considerable alteration during the course of pregnancy; a woman who is accustomed to sugar and starchy foods finding that these are distasteful and that meat and highly seasoned dishes are better appreciated and digested, or the reverse of this may be experienced. Within reasonable limits such a change of appetite indicates the special temporary requirements of her organism and may be gratified; in particular, curries and seasoned dishes may often be taken without any consequent nausea, while comparatively tasteless foods are immediately followed by vomiting. Occasionally the appetite becomes absolutely depraved (*Pica*). In this case there is usually some mental disorder or perversion, and control is not only advisable but necessary. *See APPETITE, Disorders of.*

4. *Dental Caries.*—In pregnancy there is almost always a special tendency to dental caries, so much so that 'for every child a tooth' has become a popular proverb. Nevertheless, the drift of all modern thought and investigation is to lay stress on local causes and on these alone as originating dental caries. Decomposition of the starchy foods remaining in contact with the teeth and gums, and excessive growth of micro-organisms within the mouth, are the important factors. In pregnancy (apart from salivation and occasional gingivitis) there appears to be some special predisposition to the decomposition of retained matters, and the toilet which suffices under ordinary conditions may prove insufficient during the time of gestation.

The Eastern habit of washing out the mouth, not only after every meal, but after partaking of any

food, and the careful cleaning of the teeth at night, are the methods by which this tendency may be most successfully fought against.

When caries has already started it needs prompt attention by the dental surgeon, and in weak, strumous and poorly-nourished patients the local treatment may often be advantageously supplemented by the administration of good food, hypophosphites, lime-salts, and cod-liver oil. *See TEETH, Diseases of.*

5. *Cutaneous disorders.*—The chief disorders of the skin encouraged by, or associated with, pregnancy are pigmentation, 'pityriasis versicolor,' herpetiform eruptions (herpes gestationis), and (rarely) a pustular eruption, best described as impetigo. In addition to these, the development of subcutaneous fat demands some notice. This may lead to marked alteration in the shape and expression of the face. The alteration in appearance produced by this and by excessive pigmentation is only temporary; it disappears with the termination of the pregnancy and calls for no treatment.

Parasitic skin-affections need anti-parasitic remedies. Of these, a solution of perchloride of mercury is perhaps that most generally useful. Herpes gestationis may appear at the very beginning of pregnancy, but is more often met with in the later months or immediately preceding delivery. It is attended by much itching and burning, and is usually relieved by local applications of ichthylol (5 to 10 per cent.). *See HYDROA, p. 689.*

Impetigo gravidarum occurs as an eruption closely simulating that of Variola. In one patient who was under the care of the writer, and who suffered from this eruption during each pregnancy (but not at any other time), the resemblance was so striking that her neighbours reported the case to the sanitary authority as one of small-pox. The pustules were numerous, large, and mostly discrete. The chest, back, and face were the parts chiefly affected.

TREATMENT.—In this eruption, as in several other pustular affections (such as furunculosis), the administration of lime-salts (calcium hypophosphite and sulphide) appears to be of decided value. Locally dilute ointments of ammoniated mercury (grs. v ad ʒj) or ichthylol (5 to 10 per cent.) are those most efficacious and grateful. *See IMPETIGO.*

6. *Chorea gravidarum.*—Chorea is sometimes, although very rarely, a special disease of pregnancy in that it first occurs during pregnancy and recurs during subsequent pregnancies. In most cases it must rather be regarded as an intercurrent disease which is aggravated by the pregnant state. As predisposing causes rheumatism and rheumatic surroundings are of chief importance. The dangers of chorea during pregnancy are mental exhaustion, pain, want of rest, with consequent delirium and mania, cerebral hæmorrhage, intra-uterine hæmorrhage, and incomplete abortion.

TREATMENT.—The chief drugs of any value are arsenic and chloral hydrate. When incomplete abortion has occurred and there is any danger of sepsis, the uterus must be emptied; but if this be necessary, the operation should be done so as to cause the least shock to the patient. It is well to remember that the chorea does not necessarily cease with the termination of the pregnancy. Premature delivery unless clearly indicated should be avoided.

7. *Mental Perversion.*—*See INSANITY OF PREGNANCY, p. 758.*

II. Disorders due to Pressure.—(1) Frequency of micturition; (2) Constipation; (3) Hæmorrhoids; (4) Varix; (5) Œdema of the lower extremities; (6) Cramps of the lower extremities; (7) Pruritus vulvæ.

1. *Frequency of micturition* is often complained of during the first two months of pregnancy when the enlarged fundus is lying forward on the bladder, either preventing full distension or, by its pressure, exciting a desire for urination. This always improves as the bladder becomes accustomed to the pressure, and still more so when the uterus rises out of the pelvis into the abdomen and the pressure is removed.

2. *Constipation* is an occasional difficulty during pregnancy, the pressure and stretching caused by the enlarging uterus interfering with the proper action of the rectum. The best treatment is by an aloes-and-belladonna pill given every night: Ext. Aloes Barb. gr. jss; Ext. Belladonnæ gr. $\frac{1}{4}$. A small enema should be administered every other morning if the pill is insufficient. See CONSTIPATION.

3. *Hæmorrhoids* are always made worse by pregnancy, and sometimes during the later months the pain and distress occasioned by the rectal protrusion may be severe. In such a case pregnancy need be no bar to successful operation. In milder cases the daily full evacuation of the bowels, as advised under constipation, and the local application of some preparation of Hamamelis, will afford the most relief to the patient.

4. *Varix* of the superficial veins of the thigh, labium and 'mons' is a pressure-disorder of pregnancy which sometimes causes serious disease. The enlarged veins may form a considerable tumour, which on standing or walking becomes prominent and turgid and involves the patient in the very practical danger of venous rupture, either subcutaneous or open. The treatment of this condition demands a good deal of rest in the recumbent position with the foot of the couch or bedstead permanently raised. All pressure-disorders need this. It is a good rule during all the later months of pregnancy to make the patient lie down on a raised couch or bedstead for two hours in the early afternoon. This divides the day into two short half-days and does much to obviate the evil effects of both weight and pressure. The support of a bandage, which is so useful in varix below the knee, is generally impossible of application to the upper part of the thigh and to the vulva. When the varix is sufficiently localised the dilated veins may be excised. In a very few cases the condition may be so severe and extensive as to call for the induction of premature labour.

5. *Œdema of the lower extremities* is sometimes due to pressure only, but may be due to coincident kidney-disease (see p. 216). If, on examining the urine, no albumen is found, the pelvis and abdomen should be carefully examined to see if there is any accessory or abnormal cause of pressure—such as myoma or co-existing ovarian tumour. If none be found a good prognosis may be given, and the tendency to œdema treated by position (see 4. Varix, above), by aperients, and if there be anæmia, by blood-tonics.

6. *Cramps.*—During the later months of pregnancy cramps of the lower extremities frequently occur at night. These appear to be directly due to pressure on the larger nerve-

trunks in the pelvis, and are met with most commonly while the patient is lying on her back.

Change of position is generally sufficient to relieve this distressing symptom.

7. *Pruritus vulvæ* appears sometimes to be due to the pelvic congestion accompanying pregnancy. When complained of, the case should be investigated for any possible intercurrent cause such as gonorrhœa or glycosuria. A very hot saturated solution of boric acid, freshly made, will usually allay the itching. The parts should then be carefully dried with soft rag and anointed with dilute boric-acid ointment. At night this can be applied on borated gauze and kept *in situ* after the lotion has been used.

When there is marked purulent discharge affecting the urethra as well as the vagina; when this is sudden in its onset and accompanied by much pruritus and dysuria, the possibility of gonorrhœal infection should always be considered. In this case the vagina should be well treated with suppositories of silver nitrate ($\frac{1}{4}$ gr.), and a special disinfection of the genital passages be carried out at the time of the confinement. This will diminish the risk of gonorrhœal ophthalmia. See PRURITUS.

III. Diseases due to Misplacement of the Pregnancy or of the Uterus containing the Pregnancy.—(1) Placenta prævia; (2) Retroversion of the gravid uterus; (3) Cornual pregnancy and interstitial pregnancy; (4) Extra-uterine pregnancy (and its consequences).

1. *Placenta prævia.*—DEFINITION.—A pregnancy in which the placenta is attached over the internal os or lower outlet of the uterus, and therefore in front of the child.

VARIETIES: (1) Placenta prævia centralis or totalis; (2) Placenta prævia lateralis; (3) Placenta prævia marginalis.

FREQUENCY AND CAUSATION.—The frequency of Placenta prævia is about 1 in 1,500 births (Winckel). It is very much more common in multiparæ than in women who have not had a previous pregnancy, and the pregnancy in which it occurs is stated to be often preceded by chronic endometritis.

DANGERS.—Difficult labour and fatal hæmorrhage.

DIAGNOSIS.—This is difficult or impossible in the earlier months so long as the cervix is contracted. It may be suspected (a) when sudden copious bleeding occurs at what would have been a menstrual period, and especially if this is repeated after three or four weeks' interval; (b) when no other site can be discovered for the placenta both by palpation and auscultation; and (c) when there is unusual thickness, vascularity and pulsation in the neighbourhood of the cervix. Very often bleeding does not occur until the last month of pregnancy, sometimes not until labour commences—the bleeding in placenta prævia being due to separation of the placenta (1) from development of the lower uterine segment and (2) from dilatation of the cervix.

When the cervix is dilated the diagnosis becomes easy. Instead of the presenting amniotic sac containing the liquor amnii and fœtus, there is the thick fleshy mass of the placenta intervening. In placenta prævia lateralis and marginalis the edge of this is tangible, and beyond this it may be possible to feel the amniotic sac and fœtus. In placenta prævia totalis, the cervical canal is everywhere covered by placenta.

TREATMENT.—In early and suspected cases, absolute rest in bed and the administration of a Dover's powder will usually be sufficient to check hæmorrhage. Ergot should not be given. If the bleeding continues the vagina may be temporarily plugged with salicylic or sublimate wool, and the uterus may be afterwards emptied of its contents.

In cases at a near term when the cervix is sufficiently dilated to feel the placenta and examine its attachments:—

(a) if the placenta be marginal, the membranes may be ruptured and the head allowed to descend by the side of the placenta, natural labour proceeding (as with normal placental attachment).

(b) if the placenta be central, such separation is made as will conduct the finger (by the shortest route if possible) to the amniotic sac and foetus, and the foot of the child is brought down by 'combined version' with one finger. The examining finger pushes the shoulder aside while the breech is pressed downwards by the hand outside the abdomen. This brings the feet of the foetus in contact with the finger. The membranes are now ruptured, the finger passed around one foot, and by pressure of this and the cervix against the pubes the foot is tightly held until it is conducted through the cervix. The other foot may be afterwards brought down. The body of the child now forms a plug which stops further hæmorrhage, and delivery should be allowed to proceed slowly. The rapid emptying of the uterus is not advisable. The neck of the uterus in cases of placenta prævia is often easily torn, and the hæmorrhage from a deep laceration of the cervix may prove fatal when that from the separated placenta has been practically stopped.

2. *Gravid Retroversion.* — **DEFINITION.** — A uterus at one and the same time displaced backwards and pregnant.

HISTORY. — There is usually some previous history of displacement, and pregnancy must of necessity be a possible condition. In the greater number of cases where pregnancy and backward displacement are combined, the uterus rises as the pregnancy grows and the displacement spontaneously rights itself. In the minority this spontaneous replacement does not occur, and at the end of the second or beginning of the third month serious trouble arises. The pressure of the pregnancy on the neck of the bladder and urethra causes dysuria, and after a short time complete retention of urine. If unrelieved the ureters and kidneys suffer from backward pressure, and fatal sloughing has been known to occur from the increasing pressure within the pelvis.

DIAGNOSIS. — The patient has the ordinary symptoms of pregnancy, nausea and vomiting being sometimes excessive. She probably has a history of amenorrhœa corresponding to the period of gestation at which she has arrived, and the mammary signs may be confirmatory of her condition. Dysuria or retention of urine is probably the prominent symptom.

On examination, a big, elastic, globular mass is found filling the pouch of Douglas behind the cervix and pressing this against the pubes.

On bi-manual examination with the bladder empty, the fundus is found to be wanting anteriorly and the cervix may be felt (from above as well as from below) to pass directly into the posterior tumour. The tumour itself is elastic and resilient

like a gravid uterus of the second month. The difficulty of passing urine is quite of recent date, and with the exception of 'retention,' which may be a sudden phenomenon, there is no history of acute collapse or pain or hæmorrhage (unless abortion be in progress), but the discomfort occasioned by the gravid displacement is one of gradual and steady growth.

The differential diagnosis between this condition and tubal pregnancy with intra-peritoneal hæmatocèle is one of vital importance, and no attempt at replacement of the uterus should be made until the possibility of extra-uterine pregnancy has been rigidly excluded.

Where the pregnancy is outside the uterus and the tumour in Douglas's pouch has been caused by hæmorrhage there is usually a history of rather sudden collapse and pain; pressure-symptoms may be, but are not as a rule particularly prominent; and on careful bi-manual examination (if necessary, under anæsthesia) the whole of the uterus, from cervix to fundus, is found in front, or to one side of the tumour.

TREATMENT. — The bladder is completely emptied. The cervix is seized with volsella, or bullet-forceps, and the patient is placed in the knee-chest position. The cervix is drawn downwards and backwards, and the patient is directed to breathe deeply and regularly. One or two fingers placed in the posterior fornix at the same time assist in pushing the fundus upwards and forwards.

In this way reposition may usually be directly carried out, the womb escaping into the abdomen above the pelvic brim. When this takes place, the posterior tumour vanishes and the cervix becomes directed backwards. A single large ring-pessary inserted while the uterus is in good position will prevent any danger of relapse. The pessary can be removed about the fifth or sixth month.

In cases where attempts at immediate reposition are ineffectual, the patient should be kept in bed with the foot of the bedstead slightly raised, and the urine should be regularly withdrawn by an aseptic catheter. Under these conditions spontaneous reposition usually takes place. It may be assisted by the use of a vaginal 'colpeurynter' (a dilator of indiarubber distended with water).

In a few cases the pregnant uterus may be adherent in retroflexion. If the adhesions are light they will be separated by the growth of the pregnancy or so lengthened and undone as to admit of the manual reposition of the organ. If the adhesions are too dense for this, it is better practice to open the abdomen and separate them carefully from within the peritoneum than to use force or to make repeated ineffectual attempts at replacement from without.

3. *Cornual Pregnancy and Interstitial Pregnancy.* Pregnancy in a rudimentary horn and pregnancy in the substance of the uterine wall (interstitial pregnancy) are very rare. They may be regarded as misplaced pregnancies because they are both outside the proper uterine cavity, and delivery under natural conditions is usually quite impossible. In both conditions rupture is liable to take place, when the investing sheath of tissue proves insufficient for the requirements of the growing pregnancy. This usually happens about the fourth month.

The symptoms are then those of sudden internal hæmorrhage and collapse (see 4. Tubal Pregnancy, p. 1311) combined with the history and

physical signs of a somewhat advanced pregnancy which, in general character, differs but little or not at all from the normal.

As in all true extra-uterine pregnancies, the proper uterine cavity is somewhat enlarged and contains a 'decidua' which generally separates when any disaster happens to the pregnancy. Consequently some bleeding may be taking place from the uterus and vagina at the same time as the more serious hæmorrhage is taking place internally, and this may give rise to the (mistaken) diagnosis that the symptoms are only due to an incomplete abortion.

TREATMENT.—The abdomen must be opened and the pregnancy removed. In a ruptured cornual pregnancy the base or pedicle of the pregnant horn may be ligatured by a chain of three ligatures, and the whole of the pregnant horn removed. In an interstitial pregnancy it is usually necessary to remove the uterus, but if the abdomen be opened before rupture has taken place, the pregnancy may be removed by a uterine incision and the resulting wound closed by suture (*see American Journal of Obstetrics*, xxvii. 694).

4. *Extra-uterine Pregnancy (and its Consequences).*—Nearly all extra-uterine pregnancies begin within the Fallopian tube. A very few cases have been recorded which appear to have begun within the ovary. These are very rare. In *tubal pregnancy* the fructified ovum attaches itself to the inside of the Fallopian tube (instead of the uterus), and grows in this situation. The most common result of this misplaced attachment is recurrent bleeding from the fimbriated end of the tube into the abdomen (with or without rupture) causing intra-peritoneal hæmatocele. The next most common result is rupture with sudden and diffuse intra-peritoneal hæmorrhage. Both of these occur early in the history of the pregnancy. The least common result is the continued growth of the pregnancy outside the uterine cavity. This may take place by invasion of the abdomen from the tube (*tubo-abdominal pregnancy*); by invasion of the sub-peritoneal tissues below the peritoneal reflexion (*tubo-ligamentary or broad-ligament pregnancy*); by invasion of the uterus (*tubo-uterine or interstitial pregnancy*). *See* 3. Interstitial Pregnancy.

Roughly speaking, then, the three conditions, (a) intra-peritoneal hæmatocele, (b) diffuse intra-peritoneal hæmorrhage, and (c) the special tumour caused by an advanced pregnancy outside of the uterus, are the chief phenomena of this disease, each of which separately points to some special accident or stage of extra-uterine pregnancy.

(a) *Intra-peritoneal hæmatocele*, together with the enlarged and distended tube from which the bleeding comes, usually forms a tumour which can be readily felt on bi-manual examination.

It is often retort-shaped, it occupies the pouch of Douglas behind the uterus, it fixes and displaces the uterus generally forwards and to the opposite side, and the tumour is apt to enlarge suddenly owing to fresh hæmorrhage. It is then acutely tender and the abdomen above is distended and very sensitive to touch. The attendant symptoms are those of moderate shock, anæmia, and transient peritonitis. When these signs are found in a woman who is in a position to be pregnant and who has a history of any amenorrhœa (however slight) followed by irregular loss, with or without the history of the passage of a 'decidua' or decidual

shreds from the uterus, there is strong reason to suspect a tubal pregnancy as the cause of the disease. This suspicion is increased if all the symptoms and signs are of comparatively recent date.

TREATMENT.—If the tumour be well marked on examination of the posterior vaginal fornix and evidently extra-uterine—the uterus being well differentiated to one side of the tumour—the case may be treated by posterior vaginal cœliotomy.

The hæmatocele and pregnancy are cleared away after free incision of the pouch of Douglas. If necessary, the tube may be removed by the same route. The incision is afterwards drained by a tampon of iodoform gauze.

(b) *Diffuse intra-peritoneal hæmorrhage.*—This must be recognised by its symptoms. It is peculiarly apt to occur at a very early stage of tubal pregnancy before any recognisable tumour has had time to form, but occasionally takes place at later stages.

The patient, who has been previously quite well but has gone a week or more beyond her usual 'period,' is suddenly seized with abdominal pain. Within a few hours (or less) her condition becomes serious. Her pulse increases in frequency (80, 90, 100, 110, 120, 130, &c.), and this, as a rule, without any rise of temperature; she becomes faint and pale, and the pulse, as it rises in frequency, becomes very much weaker. Occasionally it is fluttering. The abdomen becomes distended and tender, and sometimes fluctuation of the fluid blood within the abdomen may be detected by abdominal palpation and percussion. On vaginal examination it may be possible to feel either the tumour of the pregnant tube or the soft, semi-clotted blood which has collected in Douglas's pouch, and which gives a sensation of slight boggy resistance on vaginal touch.

TREATMENT.—The abdomen must be opened and the hæmorrhage stopped by ligature and removal of the pregnant tube. The abdominal section should be by incision above the pubes, and it is well to thoroughly wash out the blood and blood-clot from the abdomen by copious irrigation with hot water. The pouch of Douglas is drained with a glass drainage-tube.

(c) *The special tumour caused by a more or less advanced extra-uterine pregnancy* differs according to its position. If 'abdominal' or 'tubo-abdominal' the whole of the child may generally be felt lying within the abdomen, uncovered by any containing sac. The uterus is quite distinct from the pelvis, and is but little or not at all enlarged. A lump to one side of or above the uterus (which is neither child nor uterus) marks the substance and situation of the placenta. The fetal heart is very plainly heard if the child be living; the placental 'bruit' may be difficult to find.

If 'ligamentary' or 'tubo-ligamentary' there is generally a fairly thick containing sac—a 'pseudo-uterus'—outside the child. This is sometimes central, but often to one side of the abdomen. The uterus is necessarily attached to one part of the wall of the sac and is therefore somewhat lengthened and enlarged. The sac is not of uniform thickness, and at some point either from the abdominal or vaginal wall 'ballotement' may probably be elicited. The placental 'bruit' is usually more easy to find than the pulsations of the fetal heart, but this is not a certain guide.

Both conditions here described need careful differentiation from a normal pregnancy within a uterus whose walls are exceedingly thin. Under this

condition a foetus may appear to be quite free in the abdominal cavity when it is really within the uterus.

TREATMENT.—If no dangerous symptoms appear, the pregnancy may be watched until the natural term be nearly reached. Then, every preparation having been previously made, the abdomen is opened and the pregnancy removed. If 'abdominal,' it is probably wiser to remove both child and placenta, the latter being usually mainly attached to the remains of the Fallopian tube. If 'ligamentary,' the containing sac of the broad ligament (after incision and removal of the foetus) may often be sewn to the sides of the abdominal incision, and the placenta be allowed to separate slowly and come away in the subsequent discharges.

IV. Diseases caused by Abnormal Conditions of the Uterus itself (or of the Uterine Appendages) other than Displacement.—(1) Pregnancy in one-half of a double uterus; (2) Pregnancy complicated by myoma of the uterus; (3) Pregnancy complicated by ovarian tumour.

1. *Pregnancy in one-half of a double uterus.*—The phenomena occasioned by this abnormality vary according to the extent of the 'doubling.' If the doubling be complete, affecting both uterus and vagina, there are of necessity two vaginæ and two

all stages, especially if we include under this heading any enlargement of the ovary and not only the large cystic mass usually characteristic of ovarian tumour. The ovarian enlargement necessarily forms a swelling outside of, and in addition to, the tumour of the pregnant uterus, and this may easily be found on careful vaginal, abdominal, or bimanual examination.

When complicating pregnancy, an ovarian tumour, however small, is peculiarly dangerous; for at parturition or miscarriage, or even without this, it is specially liable to twisting of its pedicle and then becomes a source of acute peritonitis and sudden danger.

TREATMENT.—If the presence of an ovarian or tubal tumour is made out with certainty, it is advisable to remove it. Pregnancy is no bar to successful operation. If the operation be done carefully, miscarriage very rarely follows. It is the rule for the gestation to continue without disturbance. If on diagnosis immediate operation be refused, the tumour should be watched so that no confusion may occur regarding the cause of any inflammatory symptoms suddenly arising.

V. Diseases caused by Pelvic Deformity or Bony Outgrowth.—The frequency of pelvic deformity varies according to locality, being common in some cities—such as Glasgow and Manchester—and very rare in others (as in Birmingham).

—	Iliac Spines	Iliac Crests	Conj. Ext.	Conj. Diag.	Conj. Vera
1. The simple flattened pelvis . . .	25	28	18	11	9
2. The rachitic flat pelvis . . .	27–29	28	18–13	11–6	9–4
3. The generally contracted pelvis . .	23	26	18	11	9
4. The generally contracted flat pelvis	23	26	16	9	7
The normal pelvis	25–26·3	28–29·3	20	13	11

uteri—the one pregnant and the other not. If examination be made through the vagina leading to the unimpregnated uterus, the tumour of the pregnancy will appear to be extra-uterine. By successive examination of each vagina in turn, the true condition can be ascertained and any danger of mistake avoided.

When the 'doubling' affects the uterus or bodies of the uterus only, and both are pervious to the single vagina, the unimpregnated uterus will form a small tumour to one side of the pregnant uterus, the two uteri being usually set at an angle to each other, the bodies diverging.

If the outlet from the pregnant uterus be free, no special treatment will be necessary; if closed, operation is imperative. See 3. Cornual Pregnancy, p. 1310.

2. *Pregnancy complicated by myoma of the uterus.* The influence of myoma upon pregnancy depends upon its seat or position. If affecting the upper two-thirds of the uterus and free to move, it almost invariably rises with the growth of the pregnancy and does not interfere with normal delivery. If growing from or near the cervix, wholly pelvic and especially if adherent or fixed, the gravest danger may be apprehended from the complication. In these cases it is often necessary to induce an early abortion or to remove the uterus and pregnancy together.

3. *Pregnancy complicated by ovarian tumour.*—This is a complication which needs recognition at

Pelvic deformity is usually (but not always) accompanied by visible general deformity or stunted growth; consequently any small or deformed patient, any one possessing distortion of the lower extremities, any *primipara* with a pendulous abdomen, or any *multipara* with the history of difficult confinements, should be examined by inspection, palpation, and by careful pelvic measurement before attendance during her confinement. The more common forms of contracted pelvis, with the typical measurements of each, are given in the above table, which is copied from the 'Obstetric Manual' of Dührssen. The measurements are in centimetres (10 cmm. = 4 $\frac{1}{2}$ in.).

In addition to these forms of pelvic contraction, extreme narrowing and distortion may occasionally arise from *osteomalacia*, and from local bony outgrowths or tumours. In some of these cases the pelvic canal may be altogether obliterated.

TREATMENT.—The minor degrees of narrowing demand delivery by forceps or version. The major demand either the induction of premature labour or some form of Cæsarian section. In *osteomalacia* it is wise to remove the uterine appendages.

VI. Associated or Intercurrent Diseases or Disorders in their relation to Pregnancy.

(1) Cholera; (2) Small-pox; (3) Scarlet fever; (4) Typhoid fever; (5) Pneumonia; (6) Acute yellow atrophy of the Liver; (7) Diabetes; (8) Malaria; (9) Syphilis; (10) Hereditary Weakness predisposing to Tubercle; (11) Lead-poisoning; (12) Gout;

13) Renal disease and Eclampsia; (14) Appendicitis; (15) Pelvic or Abdominal Adhesions; (16) Vaginal Fixation of the Uterus; (17) Operations on the Cervix; (18) Cancer of the Cervix; (19) Sarcoma; (20) Phthisis; (21) Heart-Disease; (22) Chorea (*see* p. 1308).

All disease caused by the introduction of some poison into the system has a deleterious effect on pregnancy in direct proportion to the dose of poison and force of the (usually) resulting inflammation (hyperpyrexia). Consequently the acute exanthemata (including typhoid-fever, cholera, ague, acute yellow atrophy of the liver, pneumonia, syphilis, and acute mineral or vegetable poisoning) are all exceedingly likely to cause the death of the foetus in any woman who is pregnant.

In *cholera*, the maternal mortality is about 55 per cent. The foetus is usually killed during the stage of intoxication.

In *small-pox* (unprotected) the maternal mortality has been computed at 30 per cent. Abortion occurs in one-half of the cases. When this happens, frequently soon follows the onset of the disease, and the mortality is high. Small-pox and its dangers can, of course, be largely prevented by timely vaccination. During an epidemic, pregnancy is no bar to re-vaccination.

In *scarlatina* both mother and child weather the storm if the attack be a mild one; but some epidemics, under insanitary conditions, have been very fatal. If severe, there appears to be a special danger in this disease of puerperal sepsis following the abortion or premature confinement: 'out of 21 cases, 6 ran a mild course, and in 8 sepsis occurred with 2 deaths' (Meyer).

In *typhoid fever* the maternal mortality has been computed at 30 per cent.: 'out of 91 cases 19 died' (Brieger). Abortion is the rule. 'Out of 22 cases of typhoid, 16 aborted, and the remaining six, who had slight attacks, went on to term' (Playfair).

In *pneumonia* a double poisoning is present; not only have we the direct poison of the disease, but carbonic-acid poisoning as well from interference with normal respiration. The maternal mortality varies from 50 to 100 per cent. More than half the cases abort. 'Pregnancy is interrupted in one-third of all cases before the sixth month, and in two-thirds of all cases from the sixth to the ninth month' (Wallich).

Acute yellow atrophy of the Liver (malignant jaundice) should probably be referred to under this heading, as the cause of it appears to be a blood-poisoning by schizomycetes (Winckel). This disease is peculiarly associated with pregnancy. It is rarely or never found during the first three months of pregnancy, but is more frequent after the fifth month. It usually causes premature expulsion of the foetus (in 42 out of 68 cases, Charpentier), and in many of these cases it has been noticed that the liquor amnii and child have been stained an orange-yellow by the jaundice. The emptying of the uterus may be regarded as simply an index of the strength of the poison. It is not, as a rule, attended by any improvement in the symptoms; on the contrary, the jaundice usually increases afterwards, and the patient dies with septic coma. About half of all patients affected succumb to the disease. The proportion of deaths in pregnant women is probably much higher.

True *diabetes* has a grave effect on pregnancy. Of 22 pregnancies in 15 mothers 4 ended fatally

during the puerperium. In 7 out of 19 cases the child died (after reaching viable age) during the pregnancy, and in 2 more it died shortly after birth' (Matthews Duncan).

In *malaria* the influence of the disease on pregnancy is relative and depends on the severity of the fever. 'Abortion is more frequent in malarial than in non-malarial countries.' We have now very good reason to believe that this danger may be largely or entirely prevented by the careful exclusion of the mosquito—the carrier of the infection. *See* MALARIAL DISEASE.

In cases of chronic poisoning, whether the poison comes from without as in ague, syphilis, and lead-poisoning, or from within as in chronic nephritis, gout, and struma, we not infrequently find a special effect on pregnancy induced which needs separate consideration. This may be characterised as the state of *Habitual Abortion*. The patient becomes repeatedly pregnant and after a varying period of gestation regularly aborts. *See* LEAD, POISONING BY; and OCCUPATION-DISEASES.

Syphilis is well known as a common cause of this, and too often every case of habitual miscarriage is treated with mercury and iodides on the supposition that syphilis is the probable factor, though perhaps concealed. This is bad practice. In nearly every case where syphilis is the cause of habitual abortion, the history or trace of its presence in one or both parents is plainly discoverable. Moreover, if the mother be young, if the general health be well maintained, and if there be no continued exposure to sexual excess or fresh sources of danger, the disease tends of its own accord towards recovery, and the patient, if repeatedly pregnant, tends to go longer without abortion until a still-born or syphilitic child is born at term—no abortion having taken place.

When the evidence of syphilis is plain, then anti-syphilitic treatment should be administered to both parents (the treatment of the wife alone is altogether insufficient). This should be continued for three years and every attention paid throughout the course to nutrition and to hygiene. When no trace or history of syphilis can be found, anti-syphilitic remedies should be carefully withheld. When uncalled for, they may do decided harm.

The hereditary weakness of tubercular families is not recognised as it should be as a cause of habitual abortion. In ordinary family practice it is in many districts quite as common a cause as syphilis, but needs altogether different treatment. When this is the cause there is always some family history of tubercle (phthisis, fistula, bone-disease, lupus, tubercular meningitis, or tubercular peritonitis), and this is probably of nearly as much importance on the side of the husband as on that of the wife. When either one or both parents possess a tubercular family history—showing that there has been some special weakness of one or both families favourable to the growth of the tubercle-bacillus—and when miscarriage following conception is a frequent or habitual occurrence, the consideration of the two conditions as directly associated will usually lead the physician to right and often to successful treatment.

In such parents everything which lowers body weight and general nutrition is fatal; consequently anything which tends to enfeeble the patient, the want of good food, the continued administration of mercury or repeated miscarriage, tends to lessen

the power of successful gestation; and in a series of abortions, the later ones tend to recur at earlier rather than at later periods until, in some cases, the power of conception fails. Exceptions to this rule may occur after prolonged holidays, and after any treatment which improves the general health.

The clue which this affords to treatment is of some importance. Attention to general hygiene and especially to sufficient 'holiday life' in the open air cannot be overrated, but the main essential in treatment is the persistent administration of Cod-liver oil and Syrupus Ferri Phosphatis Compositus to one or both parents until a healthy conception takes place. The same treatment is then continued to the mother throughout the whole period of gestation. By these means in a very considerable number of cases the tendency to abortion is counteracted and a healthy child is born at term.

Lead-poisoning may be a cause of habitual abortion among workers in lead, and lead is sometimes purposely taken in order to produce miscarriage. Several fatal cases have been recorded.

Gout and chronic kidney-disease may be causes of early miscarriage, but the chronic nephritis or special kidney-disease of pregnancy usually affects the organism of the mother much more than that of the infant and is the cause of one of the most dangerous of all the disorders of pregnancy, puerperal convulsions or eclampsia. See PUERPERAL DISEASES; and ECLAMPSIA.

The chief *surgical* affections influencing pregnancy or parturition are appendicitis, pelvic or abdominal adhesions, the operation of anterior colpotomy with vaginal fixation of the uterus, and cancer of the cervix.

Appendicitis is an occasional cause of abortion, sometimes it may cause 'habitual abortion.' Appendicitis gives rise to abortion in two ways. As an acute disease it may cause septic poisoning and pyrexia, destroying the fetus in very much the same way as the acute exanthemata; and, secondly, as a chronic source of trouble through adhesions to the right appendages and right side of the uterus it may interfere with the normal progress of gestation and so induce miscarriage.

Pelvic or abdominal adhesions other than those due to appendicitis may likewise be a cause of habitual abortion, and strong adhesion or fixation of the cervix anteriorly may be a cause of difficult labour. This is an occasional result of some surgical operations on the uterus and of cancer of the cervix.

Anterior vaginal caliotomy with fixation of the uterus.—The opening of the peritoneum between the cervix and bladder and the sewing of the fundus forwards to the sides of the vaginal incision is usually (when performed rightly and with due aseptic care) an operation having no untoward sequelæ. If, however, the union be not rigidly 'sero-serous,' and if the wound become septic and there be any prolonged suppuration, it is quite possible to get such firm union and fixation as to complicate or prevent the proper delivery of a subsequent pregnancy. Under these circumstances it has been necessary on one or two occasions to perform Cæsarian section. For this reason, in the operative treatment of non-adherent retroflexions, the writer prefers and strongly recommends the shortening of the round ligaments without opening the peritoneum.

Other operations on the uterus, such as the repair of a deep laceration of the cervix or the amputation or excision of the cervix, may likewise be followed either by firm fixation or contraction; the resulting cicatricial tissue interfering with the proper discharge of the menstrual function or with the dilatation of the cervix necessary for delivery.

In one case of this kind in which the writer had to remove the uterus, the uterine tissue tore out before the adhesion would give way.

In some of the cases where there is marked obstruction in delivery the vaginal Cæsarian section of Dührssen offers a readier and less dangerous method of delivery than that by the abdominal route. The chief objection to this method consists in the occasional great difficulty of uterine suture through the vagina after delivery.

Cancer of the cervix may produce a very similar condition of rigidity and fixation to that already described as occasionally resulting from inflammation. In a few cases too, cancer of the rectum invading the broad ligament may produce an unyielding bed of tissue in which the uterus cannot properly dilate.

When such conditions are associated with advanced pregnancy Cæsarian section is the usual method of dealing with the difficulty. When found at an early stage of pregnancy the propriety of emptying the uterus may be reasonably considered.

Cancer or sarcoma may affect pregnancy in other ways. One form of sarcoma—deciduoma malignum—only occurs in connection with pregnancy or the post-puerperal period. It grows from the placental site, invades the uterus and is usually rapidly fatal. See PLACENTA, Diseases of the.

Cancer often appears to grow with increased luxuriance during the later stages of pregnancy, and in cases allowed to drift the mortality of the puerperium is very high. Forcible extraction of the child by forceps or turning is often accompanied by rupture of the uterus or bladder, and if the patient survives the hæmorrhage and shock, she may still have to encounter the dangers of peritonitis and sepsis.

Phthisis has, as a rule, less direct effect on pregnancy than the state of constitutional weakness predisposing to consumption. If a woman, already suffering from phthisis, become pregnant, her reproductive power is usually strong, and though abortion may result, it is by no means a necessary consequence.

A very considerable number of women suffering from phthisis immediately improve in health and in general nutrition after conception has taken place, and if the surroundings and diet be good, and if hæmoptysis does not occur, this improvement is maintained throughout the whole course of the pregnancy. The birth may be premature, and the child tubercular, but in most instances the pregnancy advances to term without disturbance, and the child is apparently healthy. But after the pregnancy is over there is almost always a severe relapse. The gain in nutrition is rapidly lost; the lung-disease advances, and the patient very often only lives a few months after the birth of her infant. This may to some extent be guarded against by careful management during the lying-in, but does not interfere with the general rule that the post-puerperal period is very fatal in phthisis.

In *Heart-Disease* it is also the post-puerperal time that is usually more dangerous, but the danger

varies greatly according to the disease and the presence or absence of compensatory changes.

Mitral Stenosis appears to be the most fatal of all cardiac lesions in pregnancy. Out of 54 reported cases no less than 35 were fatal, but this includes some cases of double mitral lesion.

Cases of *aortic disease* come next in importance. The mortality of pregnancy complicated by aortic disease is estimated at 23 per cent. in Norris's System of Obstetrics.

Mitral Regurgitation is of less gravity, especially in earlier years, when the patient is young and healthy. Repeated pregnancies, however, slowly tell upon the power of the heart, and the danger of the patient is markedly increased at every succeeding pregnancy. According to the same authority, the mortality of this complication is stated to be 13 per cent.

In aortic disease the most fatal period is during labour; when this is safely over there is less danger.

In mitral disease the post-puerperal period is quite as dangerous as that of labour. In fatal cases the right side of the heart has been found engorged.

Cardiac disease may induce *secondary pulmonary lesions*, both during pregnancy and in or after parturition. Of these the most important are hæmorrhage into the lung-tissue and hæmoptysis, œdema of the lungs, and congestive pneumonia. Cardiac disease is often the cause of excessive loss of blood at the time of confinement, and of faulty contraction of the uterus after delivery. The latter, by retention of blood-clot which the uterus is unable to expel, favours slow septic sequelæ.

TREATMENT.—'Pregnancy associated with cardiac disease should not be interrupted artificially.' 'The best treatment will therefore be symptomatic, and consist in administering digitalis, strophanthus, nitrate of potassium, diuretics, or diaphoretics, and in regulating the diet' (Winckel). During delivery every effort should be made to calm excitement—moderate anaesthesia—to prevent unnecessary blood-loss, and to secure good uterine contraction. Ergot should be given with caution or altogether withheld if its administration is likely to further embarrass the heart's action. During the lying-in, good nursing is of the utmost value. Psychological excitement or irritation is especially harmful, and trouble should be taken to secure the patient from any possibility of worry or anxiety.

JOHN W. TAYLOR.

PREMONITORY (*præ*, before; and *monéo*, I warn).—This word is associated with symptoms which give an indication or warning of the advent or onset of certain diseases or seizures; for instance, rigors during the invasion of fever, and the various auræ preceding an epileptic fit.

PREPUCE.—See PENIS, Diseases of; and CONCRETIONS.

PRESBYOPIA (*πρέσβυς*, an old man; and *ὤψ*, the eye).—Impairment of the power of accommodation of the eye, the result of progressive senile changes, in consequence of which the nearest point of distinct vision lies at more than nine inches from the eye. Distant vision may be perfect; but the eye, unaided by an appropriate convex lens, cannot see clearly objects less than nine or more inches from the eye. See VISION, Disorders of.

PREVENTION OF DISEASE.—See PERSONAL HEALTH; and PUBLIC HEALTH.

PRIAPISM.—SYNON.: Fr. *Priapisme*; Ger. *Priapismus*; *Ruttenkrampf*.—A continuous erection of the penis, generally unaccompanied by any sexual desire. It may be complete or incomplete. In the former case there is a rigid erection of the penis with much pain and suffering. The condition may last for many days, or even weeks or months. There are many causes of complete priapism, notably injuries to the penis which cause rupture and extravasation of blood. It may also occur in leucæmia and other toxæmias, in diseases of the brain, spinal cord, rectum, bladder, and in tetanus and hydrophobia. In incomplete priapism the penis is merely distended with blood unaccompanied by any muscular contraction, rigidity or pain. This condition is found in injuries to the spinal cord in the cervical and upper dorsal region.

TREATMENT.—In those cases where there is a collection of blood-clot this must be removed by incision. In all cases treatment is very unsatisfactory. The application of cold or heat is useful, and trial may be made of such drugs as bromides, chloral hydrate, hyoscine, and opium.

CHARLES GIBBS.

PRICKLY HEAT.—An acute eruption of minute papules and vesicles which cover the skin more or less extensively, and are attended by burning heat, and a most tormenting prickly itching. The affection occurs for the most part in hot climates, is associated with profuse sweating, and attacks principally those who are unaccustomed to extreme heat; hence it is often experienced by travellers in tropical regions. Pathologically the eruption seems to consist principally of dilatation of the sweat-ducts, caused by the blocking of their orifices. This is due to swelling of the surrounding epidermis. The papillæ are enlarged from inflammatory infiltration. The rash generally subsides in the course of a week.

PROCIDENTIA (*pro*, downwards; and *cado*, I fall).—A falling down of certain organs or structures from their natural position, as of the uterus, rectum, or iris. See PROLAPUS.

PROCTITIS (*πρωκτός*, the anus).—Inflammation of the anus or rectum. See PERIPROCTITIS; and RECTUM, Diseases of.

PRODROMATA (*πρό*, before; and *δρόμος*, a course).—A synonym for premonitory symptoms. See PREMONITORY.

PROGRESSIVE MUSCULAR ATROPHY.—SYNON.: Chronic Spinal Muscular Atrophy; Wasting Palsy; Amyotrophic Lateral Sclerosis; Chronic Poliomyelitis; Fr. *Atrophie Musculaire Graisseuse progressive* (Duchenne); Ger. *Muskelatrophie*; *Muskellähmung*.

DESCRIPTION.—Slow wasting of the muscles, beginning in some particular part, spreading and increasing, until it is wide in extent and extreme in degree. The changes in the muscles depend upon a slow degeneration in the ganglion-cells of the anterior cornua of the spinal cord, accompanied by a degeneration in the motor nerve-fibres arising from the cells. With this degeneration of the cells and fibres there is usually also associated a similar

change in the pyramidal tracts of the cord, sometimes, at least, to be traced up to the motor cortex of the brain, and related to a similar degeneration of their ganglion-cells.

Charcot has divided cases of this disease into two varieties, the so-called 'protopathic' form, in which the affection consists essentially of a primary degeneration of the motor cells of the cord, of the nerve-fibres proceeding from them, and of the muscles; and the 'deuterothropic' in which there is also degeneration in the pyramidal tracts, to which the affection of the spinal cells and fibres was thought to be secondary. To this second class he gave the name 'amyotrophic lateral sclerosis.' But the distinction is not valid. The pyramidal fibres always degenerate with the motor cells and at the same time. The two varieties are essentially the same disease. The difference between them is that, in the one case there is degeneration only of the lower, spinal, motor neuron, in the other there is also decay of the cerebral neuron, which comprises the cortical cell and pyramidal fibre.

ETIOLOGY.—Males are more frequently attacked than females in the proportion of about three to one. The disease is one of adult life, commencing as a rule between the ages of twenty-five and fifty-five. Cases have been recorded in which the affection commenced as early as twelve and as late as seventy, but most juvenile atrophies are primarily muscular. An inherited neuropathic disposition is to be recognised in a small proportion of cases, but direct inheritance of the disease is very rare. All classes of society are affected, and it is doubtful whether workers with the muscles suffer with greater frequency than is accounted for by their greater exposure to certain exciting causes. Of these, one of the most important is mental distress and anxiety, an influence especially potent in later life. Another distinct cause is exposure to wet and cold, which is a cause of so many chronic spinal diseases. Sometimes the exposure has been habitual; sometimes there has been a single severe exposure, immediately succeeded by neuralgic pain, either in the part which subsequently wastes, or in other regions. Excessive use of muscles may cause slight local wasting; it is doubtful, however, whether this influence produces general muscular atrophy. Severe concussion of the cord is a rare cause, and seems usually to act by setting up disseminated myelitis, manifested by muscular wasting combined with other symptoms. In a few cases, however, concussion has been slowly followed by typical progressive muscular atrophy. More rarely a fall, in which a limb has been injured, has been followed by muscular atrophy commencing in that limb. Syphilis is an occasional antecedent, and no other cause may be traceable. In the cases in which atrophy has followed an acute specific disease such as measles, the malady is probably a chronic neuritis. Lead-poisoning may produce chronic muscular atrophy, as well as the common acute paralysis with rapid wasting. The chronic form closely resembles ordinary progressive muscular atrophy in seat and features, differing from the acute extensor palsy. In many cases no cause for the disease can be discovered. It seems then to be a premature failure of vitality in the nerve-elements concerned.

ANATOMICAL CHARACTERS.—The muscles are reduced in size and pale in colour. Parts may be hardly distinguishable from adjacent fat. On the

other hand, the muscle may be dark as a whole, and pale streaks in it may mark the position of local degeneration. There are four well-defined microscopic changes in the fibres: (1) Simple narrowing, with little or no change in the striation. The striae sometimes appear to be farther apart than normal, or the fibrillary segmentation is unusually distinct. (2) Simple fatty degeneration, the transverse striation giving place to granules, mixed ultimately with fatty globules. (3) So-called 'vitreous degeneration,' probably a distinct process from fatty degeneration. The sheath, in such a condition, contains only a clear material enclosing a few fatty globules and a few faint transverse striae. (4) A longitudinal striation develops in the fibre, with which at first the transverse striation co-exists. As the latter becomes more and more faint, the fibre comes to have the appearance of a fasciculus of longitudinal connective-tissue fibres. This change may sometimes be present alone. Fatty globules may accumulate between the fibres, with, in some cases, granules and masses of reddish-brown pigment. The interstitial nuclei are often increased, and sometimes the interstitial tissue. The capillaries may be dilated and distended. Muscular fibres, practically unaltered, may often be seen side by side with others profoundly changed. The sheaths finally become empty and shrink, and may be scarcely distinguishable from the interstitial tissue.

There are many degenerated fibres in the peripheral nerves. These can be traced to the anterior roots, which are diminished in size. The amount of degeneration in them corresponds to the wasting present in the muscles. The posterior roots are unaltered. The spinal cord is often softer than natural at the affected part, and the white substance of the lateral columns is grey and translucent. With the microscope, after due preparation, the anterior cornua are seen to be much changed at the level at which the nerves to the muscles most affected are given off. Most of the large cells have disappeared, or are represented by small angular bodies. Frequently a few large cells can still be seen, but most of these have lost their processes, and are more globular than normal. The interstitial tissue is also increased.

There is distinct degeneration in the anterior root-fibres passing from the cornu through the anterior column. A few fibres may remain, but whole fasciculi appear to be replaced by fibrous tissue. There is also usually distinct degeneration of fibres in the anterior commissure.

In the white columns there is usually considerable, often almost complete, degeneration of the pyramidal tracts, anterior and lateral, and the resulting sclerosis extends, in slight degree, beyond their limits. The degeneration can often be traced up through the decussation of the pyramids, and even through the pons and crus to the internal capsule. By the products of degeneration it has even been traced through the white substance to the cortex. But it has also been found to cease at the crus or at the medulla.

In cases in which bulbar symptoms have been present the motor nuclei in the medulla have shown changes similar to those present in the grey matter of the cord. In other cases the changes in the nuclei have been slight; but in such cases the degeneration of the pyramids has been extreme, and no doubt has involved the fibres connecting those nuclei with the cortex. The sympathetic nerves

and ganglia, when examined, have shown no considerable alteration.

SYMPTOMS.—Wasting and weakness usually come on together; but in parts not readily observed, such as the shoulder, the loss of power is frequently noticed before the wasting has been apparent. In the hand, not infrequently impairment of the power to carry out some fine action, such as writing, draws attention to the wasting.

The disease commences in the upper limb in nine-tenths of the cases, and almost as often in one arm as in the other, and as frequently in the hand as in the shoulder-muscles. From the part first affected it spreads to the other muscles of the limb. In the hand, the thenar muscles and interossei are usually the first to suffer, and of the latter the abductor indicis is usually most conspicuously affected. Occasionally the disease begins in the forearm, especially in the extensor muscles; the ulnar extensors then suffer most. Of the shoulder muscles, the deltoid is generally the first to waste; the supra- and infra-spinati are often affected with it; and the triceps usually suffers less and later than the biceps.

The muscles of the back are in most cases early involved in the wasting. The middle and lower parts of the trapezius suffer first, the rhomboids and erectors of the spine later. The serratus, latissimus, and pectoralis major are subsequently involved, but they may escape wholly or in part. According to the affection of the muscles connected with the capula, the position of the bone changes. The highest part of the trapezius shows sometimes (but not always) a remarkable indisposition to waste, and it was hence termed by Duchenne the *ultimum moriens*. The muscles that extend the head on the spine often suffer in considerable degree, and a difficulty in the carriage and movement of the head is the result. The increased efforts of the weak extensors to balance the head on the spine, under such conditions, often cause a synergic over-action of the frontales, which are habitually associated in action with the extensors. The skin at the back of the neck lies in transverse folds when the head is put back. In striking contrast to the wasting of the neck is the condition of the platysma, which always escapes, and not uncommonly undergoes hypertrophy as if in an attempt at compensation. The muscles of respiration suffer in the majority of cases, and their implication constitutes a grave source of danger to life. The intercostals rarely escape altogether, and the diaphragm is involved in many cases. The muscles of the abdominal wall occasionally waste, but far less frequently than those of the thorax.

Wasting in the legs is much less common than in the arms, and if it occurs is usually slighter in degree; occasionally the disease first manifests itself in the legs, and is more intense there than elsewhere. The face almost always escapes the general atrophy, and its normal appearance may present a striking contrast to the rest of the body. But the lips and tongue often become paralysed as part of the bulbar palsy which so often supervenes on the spinal disease.

As the wasting progresses, hollows and prominences, normally invisible, become manifest, and various contractions and deformities occur as a result of the unequal affection of antagonistic muscles. In the hand the usual deformity is that of the 'claw-hand,' a result of paralysis of interossei,

with unantagonised action of their opponents. Lordosis is common when the muscles of the trunk and thigh are involved.

The electrical irritability of the affected muscles varies in character. The rule is that, in a slowly progressive case, there is diminution in the readiness and degree of response to each current, a diminution which goes on *pari passu* with the wasting, until finally, when the wasting is extreme, it becomes extinct. But the voltaic irritability of the muscular fibres very often persists long after it is impossible to elicit any response to faradism, which acts only on the nerve-fibres. Although the quality of the voltaic irritability is usually normal, the qualitative change of the 'reaction of degeneration' without the quantitative may be present. When the affection is rapid in its course, the muscles may retain considerable voltaic irritability long after that to faradism has become extinct, and a typical reaction of degeneration may be present. Between the extreme forms various intermediate conditions may be met with.

The mechanical irritability of the muscles is considerably increased, and spontaneous flickering—the so-called 'fibrillary twitching'—in the muscles is frequent, but not invariable. It is not uncommonly observed in muscles not yet wasted, but in which atrophy subsequently occurs.

The myotatic irritability in cases in which there is 'atonic atrophy,' the muscles being flaccid and toneless, is lost, and lost early. But where there is rigidity from the first ('tonic atrophy'), even when the wasting is considerable, the myotatic irritability is preserved and sometimes increased, but the wasting does not attain the extreme degree of the 'atonic' form, and faradic irritability is not lost.

Beyond the vague pains already referred to, which sometimes occur in the region in which wasting of the muscles is afterwards perceived, there are no sensory symptoms. 'Numbness' and 'deadness' may be occasionally complained of, but cutaneous sensibility is never impaired, nor do the muscles lose their sensibility.

The functions of the sympathetic are not, as a rule, impaired. Dilatation or contraction of one pupil has been observed, chiefly in connection with atrophy of muscles that are supplied from the lower part of the cervical region. The reflex action of the iris is usually normal, and optic nerve-atrophy never occurs. Nystagmus is rare.

The visceral functions are usually little disturbed. Sexual power, indeed, may be lost, but the sphincters rarely suffer, even when the wasting is extreme. Slight, but inconstant, changes have been found in the urine. Glycosuria has been associated with bulbar symptoms, but only in a few instances.

COURSE AND COMPLICATIONS.—In most cases the malady is steadily progressive, but the rate at which it advances varies much. It may, however, become stationary; unfortunately the period at which this most frequently happens is in the later stages of the disease, when little but life remains. Sometimes progress ceases at an earlier stage, especially when the atrophy is strictly symmetrical. When its course at the commencement of the wasting is rapid, it usually continues rapid until it has attained a wide extent. When it begins slowly, it continues slow throughout, but there is rarely any acute paralysis of some particular group of muscles, which may come on in a few days. The extensors of the wrist and fingers are the muscles most

commonly affected in this way. When there is weakness of the legs without wasting (spastic paralysis), the onset of this may coincide with the atrophy of the arms, or may succeed it at any interval. It is rare for the weakness in the legs to occur first.

The most frequent complication of progressive muscular atrophy is bulbar paralysis, the result of a degeneration of the bulbar nuclei similar to that in the spinal cord. In rare cases muscular atrophy in the arms is accompanied by the symptoms of locomotor ataxy in the legs; and general paralysis of the insane has been met with as an exceptional complication. Severe and frequent headaches are occasionally present throughout the course of the disease.

The chief danger to life is from pulmonary disease when the medulla is involved, induced by the entrance of particles of food into the lungs, or by bronchial catarrh, both of which are rendered grave by weakness of the muscles of respiration. Bulbar paralysis also is a frequent cause of death, by its interference with swallowing and nutrition. Less commonly, death results from profound weakness, bedsores, and septicæmia, or from intercurrent maladies which would otherwise be trifling.

PATHOLOGY.—The constancy of the association of changes in the motor cells of the spinal cord, degeneration of the motor root-fibres, and wasting of the muscles, together with the analogous effects of focal lesions of the anterior cornua, leave no doubt of the relation of the muscular wasting to the disease of the cells and of the fibres proceeding from them. The condition of electrical excitability, its slow failure as nerve and muscle degenerate together, is explained by the slowness of the change in the nerves, permitting a similar rate of degeneration in the muscle. It is only when the usual slow process is varied by a more acute change in the cells and fibres, that the muscular tissue is for some time less damaged than the nerve-structures, and so presents paralysis in excess of wasting, and voltaic irritability in excess of faradic. Thus a slow decay of the lower neuron of the motor path is the essential lesion in this disease, to which the conspicuous symptom is merely secondary. But the disease is rarely limited to the lower neuron. The pyramidal tracts, as already stated, are commonly degenerated, and it is probable that the degeneration usually involves the motor cells of the cortex. There may be no symptoms to suggest such a condition. The degeneration of the lower segment causes such atonic atrophy of the muscles as to prevent the usual manifestations of disease of the cerebro-spinal neuron. The latter may be presented as spastic paraplegia when the spinal neuron for the legs is unaffected. The relative degree in which the two neurons are affected varies considerably, and gives rise to corresponding variations in the degree of atrophy with atony, or spasm without atrophy, or with only such as is moderate in degree.

In some cases the muscular wasting is considerable, although there is rigidity and excess of myotatic irritability. In this condition of 'tonic atrophy' it is common to find that many nerve-cells have disappeared or are very small, while others remain normal or slightly changed in aspect. We have then apparently, in addition to the degeneration of the upper neuron and the nutritional changes mentioned, a considerable degeneration of many but not of all the elements of the lower neuron. This cannot be regarded as simply secondary to the

degeneration of the upper segment. It must be the expression of a distinct pathological tendency similar to that which elsewhere causes the atonic atrophy and total wasting, but insufficient to prevent the less affected cells from causing rigidity under the influence of the degeneration of the upper segment. It is doubtful whether the tonic atrophy ever goes on to atonic atrophy. The rigidity which is the effect of degeneration of the upper neuron is not produced if the lower is already so much changed as to abolish myotatic irritability. And yet the pyramidal tracts are constantly found degenerated, although the muscles have been flaccid to the last. In the rare cases in which muscles with atonic atrophy become rigid towards the end of the process, this seems to be the result of changes in the muscles themselves, and is not directly dependent upon the central nervous system.

DIAGNOSIS.—The diagnosis of the developed disease is simple. Doubt is only likely to arise in the early stages and when limitation to the one group of muscles raises the question whether the origin of the wasting is local or central. Such local atrophy is generally the result of an affection of peripheral nerves; and paralysis due to disease of a single nerve, or a plexus, will usually be recognised by its limitation and often by associated sensory symptoms. The distinction of some forms of multiple neuritis is much more difficult. This is especially the case when there has been a subacute onset, such as is common in neuritis, and this difficulty is increased by the fact that neuritis may affect only motor branches, as in lead-palsy. But the subsequent slow wasting of other parts usually renders the character of the spinal disease evident. In cervical pachymeningitis, which may cause extensive muscular atrophy in the arms, the association of sensory symptoms is distinctive, and the same applies to tumours of nerve-roots. Disseminated myelitis may cause widespread muscular atrophy, but symptoms of irregular damage to other than motor parts of the cord are also present. In syringomyelia, atrophy may occur indistinguishable from that in the disease now under consideration, but a careful examination will reveal the peculiar disturbance of sensibility, the loss to pain without loss to touch, characteristic of this condition.

The distinction from idiopathic muscular atrophy, especially when this begins late in life, is sometimes difficult. This is only true of the cases where no pseudo-hypertrophy is present. The characteristic distribution of the wasting, especially its commencement in the legs, its very slow course, and the tendency to affect other members of the same family, will usually suffice to distinguish the idiopathic form. Whenever several cases of muscular atrophy occur in the same family, or atrophy begins during childhood or youth, the probability is great that the affection is idiopathic and not spinal.

PROGNOSIS.—The nature of the disease renders the prognosis in every case grave and uncertain. The chief factors in forming an opinion are the observed progress of the disease, and the age of the patient. The possibility of arrest is greater in middle life than in advanced age. It also seems to be greater in cases in which the wasting is symmetrical than in those in which the two sides are irregularly affected. Spontaneous cessation rarely tends to take place until an advanced stage is reached, but arrest by treatment may take place at any period. Bulbar symptoms increase the gravity of the pro-

gnosis; and weakness of the respiratory muscles, especially combined with an affection of the medulla, is a most grave indication. If the malady ceases to advance, there may be a slight amount of recovery of power, especially if the loss has been rapid and recent. Wasting that has existed for some months will probably remain unchanged. In a typical chronic case there is little hope of any actual recovery of tissue or power, as these depend upon destruction of nerve-elements which seem incapable of restoration, and the definite arrest of such a disease is a far more satisfactory therapeutical result than it can possibly seem to the sufferer.

TREATMENT.—Favourable conditions of life—fresh air, gentle exercise, the absence of mental strain—are essential. Nervine tonics, suited to degenerative processes, should be given, especially quinine and arsenic, alternated with phosphorus. But the only agent which has repeatedly arrested the disease is the hypodermic injection of strychnine, first advocated for this purpose by the writer. His results have been amply confirmed. It is especially in cases which begin between thirty and fifty that the treatment has been successful. In senile cases it has seldom done more than arrest the disease for a year or so. Administration of the drug by the mouth has not the same effect, and failure by the mouth does not lessen the prospect of good from its subcutaneous use. It may be that the drug, administered hypodermically, is brought more rapidly in contact with the nerve-elements, and acts on their nutrition with a relatively greater momentum. It is best to give one injection daily (or two in some cases), at any convenient place. The most convenient salt is the nitrate, and the dose should be $\frac{1}{10}$ of a grain increased to $\frac{3}{10}$ or $\frac{1}{5}$. After four months it is well to intermit the injections for one week in three or four. The treatment needs to be continued for six or twelve months, and, with intermissions, for the same or a longer period. Other nervine tonics, as arsenic, may be given by the mouth at the same time. In a malady so grave it is desirable to neglect nothing that may have a beneficial influence.

Local treatment has not much effect on the wasting. Electricity and massage are of some service, but have no influence on the essential disease. The constant current is that which is in general of most service, but faradism may be used if the muscles respond to a strength of current which is not painful.

No special bath-treatment is of service. Antisyphilitic treatment invariably fails in cases of the true disease, and, if energetic, may accelerate its progress. The writer has twice known the malady to develop after a course of thorough mercurial treatment. It is otherwise, of course, in cases of syphilitic pachymeningitis, which should not, however, be confounded with the disease. The degenerative sequelæ of syphilis are the result of a sequential toxin, and its effects are not lessened by treatment for syphilis. It is important that this should be noted.

W. R. GOWERS.

PROLAPSUS (*pro*, forward; and *labor*, I slip).—This word signifies that an organ or structure has fallen or slipped down, but implies a greater degree of displacement than *procidencia*; so that the organ or structure may protrude through a natural or artificial orifice. The condition is of

most importance in connection with the rectum and the uterus. See *PROCIDENTIA*; *ANUS*, Diseases of; and *UTERUS*, Diseases of.

PROPHYLACTIC } (*πρό*, before; and *φυλά*
PROPHYLAXIS } *άσσω*, I guard).—These terms are used in connection with treatment, and indicate the means employed for the prevention of disease. See *PERSONAL HEALTH*; *PUBLIC HEALTH*; and the articles on the special diseases.

PROSOPALGIA (*πρόσωπον*, the face; and *άλγος*, pain).—Prosopalgia signifies pain about the face. It may depend upon neuralgia of one or more branches of the fifth pair of nerves (see *TIC-DOULOUREUX*). Its paroxysmal character, unilateral position, and anatomical localisation will indicate this form. Another form is of rheumatic origin. In this the pain is more or less constant, diffused about the face or forehead, and does not follow the course of a nerve-branch. Movements, and especially stooping, increase it. Occasionally such pain is of syphilitic origin, and is especially apt to occur in connection with the appearance of the secondary rash.

DIAGNOSIS.—In rheumatic prosopalgia the pain is diffused and increased by pressure. If it depend on syphilitic periostitis there will be tenderness on pressure, and the parts will be swollen and less elastic than normal. There will also very likely be a certain amount of fever; and the pain will be increased at night.

TREATMENT.—Chloride of ammonium in half-drachm doses, dissolved in half a tumbler of water, should be given every four hours. If there be any evidence of syphilitic infection, iodide of potassium should be given, in doses of from ten to twenty grains every four hours.

For the rheumatic form of face-ache five grains of iodide of potassium, with thirty grains of bicarbonate of potassium, may be given every four or six hours, after the administration of an aperient. This may be followed up by sulphate of quinine or iron. Locally, a mixture of equal parts of camphor, chloral hydrate, and menthol, rubbed down together in a mortar, may be applied; or a liniment containing chloroform, belladonna, and opium. Decayed teeth should be properly treated. See *PAIN IN VISCERAL DISEASE*; and *NEURALGIA*.

T. BUZZARD.

PROSTATE, Diseases of.—**SYNON.**: *Fr. Maladies de la Prostate*; *Ger. Krankheiten der Prostate*.

GENERAL RELATIONS.—The points of practical importance in connection with the anatomy of the prostate are as follows: In the examination of the rectum the healthy prostate is felt as a firm substance in the middle line, somewhat divided into two lateral lobes. The whole organ is about $1\frac{1}{2}$ inch in width, with its apex opposite, namely, in the recumbent posture below, the apex of the pubic arch; that is, about $1\frac{1}{2}$ inch from the anus, in a moderately thin subject, but much farther in a very fat one. The whole gland is $1\frac{1}{2}$ inch in length, its posterior limit being usually about three inches from the anus—in other words, about the distance to which the forefinger can reach. From this it may be deduced that, as the *trigonum vesicæ* commences immediately behind it, a fully distended bladder masks more or less completely the natural

outline of the gland. It may also be gathered that the vesiculæ seminales are beyond the ordinary reach of the finger, and that when these are infiltrated by disease, their apices alone, or perhaps only the vasa efferentia, can be detected. The practitioner should by no means neglect the digital examination of the prostate, as it will often yield information of the greatest value; and it may be observed that the best position for the patient, if it be desired to compare the relative size of the lobes of the prostate, is the supine, or the genupectoral; whereas, if it be required to explore the rectum as far up as possible, the patient should be placed on one side with the hips flexed. The deviations from the normal type he may expect to meet with are—uniform or partial enlargement from simple hypertrophy, or from chronic or acute inflammation, in the latter case possibly attended by a sense of yielding or fluctuation, due to abscess; irregular hardness, most marked about the vasa efferentia, depending on a tubercular deposit; the existence of small hard nodular masses, which are calculi in the substance of the gland, and which may sometimes be felt grating against one another; or the irregular enlargement caused by a new-growth. It must be borne in mind that tumours or abscesses originating in neighbouring parts may surround the prostate and completely obscure its outline; thus the writer has met with the case of a large hydatid cyst between the rectum and the bladder that rather closely simulated malignant disease of the prostate, and effectually prevented its actual condition from being determined. It will not be forgotten that a certain degree of tenderness of the prostate does not imply a deviation from health, and that a more or less considerable enlargement in old age is so common as to be practically reckoned by some authors as normal. The effect of this enlargement on micturition will be mentioned farther on. The copious plexus of veins which surrounds the prostate communicates freely with those of the penis and rectum; and it is not unimportant, from a clinical point of view, to remember that these are thus connected not only with the systemic but with the portal circulation. These veins may become the seat of phlebitis and its sequelæ from various causes.

The principal diseases of the prostate may be considered in the following order:—

1. **Prostate, Hypertrophy of.**—The results of Sir Henry Thompson's observations were, that one-third of all men over fifty-five have some enlargement of the prostate; but that a comparatively small number of these suffer any inconvenience from it; and that it usually begins between the ages of fifty-seven and sixty—rarely, if ever, before, though it may more rarely commence later. Very considerable enlargement of the lateral lobes may cause no inconvenience; but if the part which forms the floor of the prostatic urethra, the so-called middle lobe, be even slightly enlarged, or if, as has been shown by McGill, a ring of prostatic tissue be formed at the neck of the bladder, difficulty in micturition is sure to result. It is thus easy to understand how a simple hypertrophy may reach enormous dimensions without giving rise to symptoms, while those which are caused by the enlargement of a prostate, which feels almost normal to the finger introduced into the rectum, may, on the other hand, be very severe indeed.

SYMPTOMS.—The symptoms are briefly these:

The stream of urine becomes dribbling, and there is an obvious difficulty in emptying the bladder; there is frequency of micturition, especially at night and in the early morning; perhaps a little pain before the act, but none afterwards; and no alteration in the character of the urine. If unrelieved, these early symptoms are followed by incontinence, depending upon over-distension of the bladder; and, from the same cause not improbably, cystitis and dilatation of the bladder, dilated ureters, and, perhaps, pyelitis and chronic interstitial nephritis. Patients with chronic hypertrophy of the prostate usually suffer from time to time from attacks of acute congestion, such as are described later on. See PAIN IN VISCERAL DISEASE.

ANATOMICAL CHARACTERS.—The structure of a hypertrophied prostate is but a slight modification of that of the gland itself; but sometimes the glandular element predominates, sometimes the muscular. Distinct encapsuled tumours are often found in hypertrophied prostates, which may be either fibromyomata or adenomata. The latter are occasionally pedunculated.

TREATMENT.—In regard to treatment of hypertrophy of the prostate it is only necessary here to give two words of warning. First, that most of the evils resulting from this condition depend upon the fact that the bladder is never emptied. It is essential, therefore, that the patient's powers in this respect should be ascertained without delay by catheterisation, and if it be discovered that more than an ounce or two of residual urine remains, he should be taught to pass an instrument himself, and directed to do so at least once a day. Secondly, cystitis has often been caused by setting up decomposition of the urine by a catheter not surgically clean. The simple precautions of washing it before and after use in an antiseptic solution (say 1 to 20 carbolic acid, or 1 to 2,000 sublimate), and of applying some really trustworthy antiseptic or aseptic lubricant, will avert with certainty this catastrophe, and prevent the unnecessary loss of many lives. Nothing can be safer or less irritating for the latter purpose than oil recently boiled. The reader must consult surgical works as to the difficulties which an enlarged prostate offers to the introduction of a catheter, and the manner in which they may be overcome. A method of removing the middle lobe or the ring of prostatic tissue, referred to above, has been suggested and practised with success; and cases have been recorded in which practically the whole gland has been enucleated with complete relief. Removal of the testicles has been followed by great diminution in the size of an enlarged prostate, and has been accordingly recommended in very troublesome cases. Division of the vasa deferentia in the groin has also been practised, and apparently sometimes with success, though often no reduction of the size of the prostate has occurred in consequence.

2. **Prostate, Congestion of.**—Congestion is a condition which follows on chronic hypertrophy, and is commonly known as 'an attack of the prostate.'

SYMPTOMS.—An old man, probably but not always suffering from the symptoms already described, is suddenly seized—as the result of some indiscretion in diet, an exposure to cold, or some other apparently trivial cause—with complete retention, accompanied by bloody urine, possibly a raised temperature and quick pulse, and considerable

local uneasiness. If the case do not improve, and especially if the urine be allowed to decompose, the tongue becomes dry and brown, the pulse more rapid and weak, and the patient passes into a low typhoid condition, which is not unlikely to end fatally.

TREATMENT.—The patient must be put to bed and kept in the recumbent posture till the attack has passed off. The treatment is in large measure surgical, consisting in the proper passing of catheters. Scarcely less important are the careful regulation of the bowels and the administration of a diet sufficiently light, and yet not too lowering, together with, in most cases, a certain amount of stimulant, for it must be remembered that the patient is probably weak, and that death from asthenia is much to be dreaded. The writer would again urgently insist on the importance of preventing decomposition of the urine, which is the most fertile source of death in such cases; he can affirm from experience that this end may be attained by the thoughtful employment of antiseptic treatment, even in those cases in which it becomes necessary to keep the bladder empty by tying a catheter into the urethra.

3. Prostate, Chronic Inflammation of.—

SYNON. : Chronic Prostatitis.—This is not an uncommon affection among young and middle-aged men, depending most frequently on a prolonged gonorrhœa, in which the prostatic part of the urethra has been involved.

SYMPTOMS.—The symptoms of this disease resemble rather closely those depending upon stone in the bladder, namely, more or less frequent micturition, with a feeling of heat and weight in the perinæum, and pain, not usually severe, along the penis, extending to the tip; there is also at times a little blood passed at the end of micturition; and all the symptoms are aggravated by exercise. Generally there are frequent nocturnal emissions. The urine is cloudy, and on standing yields a muco-purulent deposit containing small white filiform shreds. A rectal examination shows that the prostate is enlarged, sometimes very slightly, and seldom to any great extent; it is always tender, but the tenderness is not, as a rule, great. The diagnosis can scarcely be made without passing the sound.

TREATMENT.—The treatment consists in rest, the administration of laxative medicines, and the application of blisters or some other form of counter-irritation to the perinæum; alcoholic stimulants are to be avoided; and the urine should be rendered bland by alkalis and diluents, as in cases of urethritis.

4. Acute Inflammation of the Prostate.—

SYNON. : Acute Prostatitis.—Acute prostatitis may arise as the result of a gonorrhœa, or of cystitis; from the irritation produced by calculi or other mechanical causes; perhaps sometimes idiopathically, or from exposure to cold or wet; and from undue sexual excitement, or the too free use of alcohol if gonorrhœa be present. It may occur in men of any age, and is accompanied by symptoms such as those depending on chronic inflammation, but much more intense; the frequency of micturition and pain during the act causing sometimes almost unbearable agony, and the dysuria amounting in some cases to complete retention, while the tenderness of the gland is very great, a condition which makes an action of the bowels very

painful. Such cases may terminate by becoming chronic; they may undergo complete resolution; or suppuration may occur. In any case there will probably be some elevation of temperature, and in the event of the formation of abscess there may be great and sudden rises and falls, accompanied by rigors and sweatings, with a dry, brown tongue, forcibly suggesting pyæmia. Rectal examination reveals a large, hard, and excessively tender prostate. The enlargement may be symmetrical or unilateral. If an abscess have approached the surface, its position will be indicated by a soft boggy sensation. Prostatic abscess may burst into the rectum, bladder, or perinæum.

TREATMENT.—The treatment of acute prostatitis consists in rest, and carefully regulated diet; diluent and alkaline medicines; purgatives; local blood-letting from the perinæum, by leeches or otherwise (some French surgeons have recommended the application of leeches to the interior of the rectum); with hot fomentations, and morphine suppositories. If an abscess forms it may be opened through the rectum, but it is better to incise it through the perinæum, as this plan is most likely to prevent the formation of that most troublesome and almost incurable condition, a recto-vesical fistula.

Abscesses sometimes form *around* the prostate (periprostatic). They are not so likely to involve the danger of the formation of a recto-vesical fistula; and they should be treated by early incision.

5. Prostate, Tuberculosis of.—This, though not a very common affection of the prostate, occurs perhaps more frequently than is generally supposed, and is of great interest, not only on account of its special features, but because it is usually a part only of a more or less general affection of the genito-urinary tract. Thus in cases where the epididymes are hard and swollen and the cords knotty from tubercular deposit, the finger introduced into the rectum will probably detect a hard nodule in one or both of the vasa efferentia. This, if seen *post mortem*, is found to consist of a tubercular or cheesy mass, and if the condition have advanced farther, the prostate itself may have become involved: there may be either separate nodules of tubercular deposit in a more or less advanced state of cheesy or, more rarely, calcareous degeneration; or the whole gland may have become hollowed out into an irregular cavity, filled in part with cheesy material, and discharging pus.

SYMPTOMS.—This disease may begin in childhood, or in adult life. Its symptoms are most obscure. At first there are probably none at all; but as the disease advances, there will arise those of tumour of the prostate, together, perhaps, with those of abscess; that is, there will be occasionally blood, and generally pus, in the urine; frequency and pain in micturition; tenderness and swelling in the rectum, and so forth. Abscess from this cause has been known to burst into the peritoneum.

TREATMENT.—The treatment can only be palliative, and must be directed to the relief of the symptoms as they arise; but at the best it is unsatisfactory. Occasionally it may be possible to open a tubercular abscess through the perinæum, but it is doubtful how far such a procedure is to the advantage of the patient.

6. Prostatic Calculi.—These are small bodies, generally multiple, formed in the glands of the prostate, usually late in life, but occasionally in

comparatively young men. They probably begin as a deposit of animal matter; but later they are made up principally of phosphate, and partly of carbonate, of lime. They may produce no symptoms at all, or they may project into the urethra, and give rise to great irritation at the neck of the bladder, and the symptoms of vesical calculus; such will also be present if, as sometimes happens, they convert the whole gland into a single cavity, in which the calculi lie side by side. In this case they will be felt through the rectum, rubbing against one another; and indeed prostatic calculi, unless they be very small, are, as a rule, to be felt in this situation. See CONCRETIONS, p. 334.

Vesical calculi of considerable size may become encysted in the prostate; and, on the other hand, prostatic calculi may find their way into the bladder. Prostatic calculi may give rise to abscess.

If any treatment be required, it is purely surgical, and must consist in the removal of the stones by forceps, a lithotrite, or a perineal incision.

7. Prostate, Phleboliths of.—The pathologist very often meets with phleboliths in the veins surrounding the prostate, the result no doubt of old phlebitis.

8. Prostate, Tumours of.—The so-called *fibrous tumours* of the prostate are in all probability simply local hypertrophies, and are composed principally of plain muscular tissue. *Cystic disease* is described as a pathological rarity, the gland being occupied by numerous cysts, containing serous or mucous fluid. *Melanosis* of the gland has also been observed. *Cancer* of the prostate occurs not very infrequently, and is usually soft, though it is sometimes hard enough to be worthy of the name of scirrhus. The writer would speak with great caution of malignant tumours of the prostate; such as he has himself examined have been cancers, with a very irregular arrangement of both stroma and epithelial cells.

Tumours of the prostate may be at present considered as beyond the reach of surgical interference, though suggestions for their removal have been gravely made in Germany.

9. Prostate, Atrophy and Absence of.—Atrophy of the prostate is said to occur as the result of pressure, sometimes from an unascertained cause, or from simple senile decay. Congenital absence of the prostate has also in rare cases been observed, but is of little clinical interest.

R. J. GODLEE.

PROSTRATION (*pro*, forward; and *sterno*, I stretch).—In medical science this word is used to express a condition of system in which the bodily energies as a whole, or the more active of them, have so completely succumbed to the effects of injury, disease, or powerful emotional influences, that they cannot be made to respond to ordinary stimuli. See COLLAPSE; DEBILITY; EXHAUSTION; SHOCK; and SYNCOPE.

PROTAGON.—See LECITHIN.

PROXIMATE CAUSES (*proximus*, nearest).—A synonym for the immediate or exciting causes of disease.

PRURIGO (*prurigo*, the itch).

DEFINITION.—Prurigo is a severe and chronic disease of the skin, characterised by intense

pruritus, and the formation of large, pale, scattered papules.

HISTORY AND SYMPTOMS.—Prurigo is comparatively rare, and until lately was overlooked as a distinct disease by English writers, who usually described cases of it as those of congenital eczema. This is explained by the fact that the disease is often masked by a great deal of superadded eczematous eruption, which is much aggravated by the scratching of the patient. 'In every case,' says Hebra, 'the earliest appearance is that of sub-epidermic papules as big as hemp-seeds, and recognised rather by touch than by sight, since they rise but little above the level of the skin, and do not differ from it at all in colour.' The development of these papules is attended by intense itching, and consequently the tops of the more prominent ones are soon scratched off, and a little drop of blood escapes, forming a small dark crust at the summit of the papule; this gives to the disease one of its characteristic appearances. When the affection has lasted for a considerable time, we notice that the skin becomes dark from increased pigmentation, and at the same time thicker and harder than normal, so that it is difficult to pinch it up between the finger and thumb; the parts affected become more or less eczematous, so that the eruption is somewhat masked; and the lymphatic glands in the groin become enlarged.

The regions of the body most commonly affected are the trunk, the buttocks, and the extensor surfaces of the limbs, especially the forearms and the legs below the knees. The scalp, the armpits, the flexor sides of the wrists and elbows, the palms and soles, groins, and hams are generally unaffected, even in severe cases. The lines and furrows of the skin become more plainly marked than normal on the parts attacked; this is especially noticeable on the backs of the wrists and on the forehead, which gives the patient a peculiar expression when the face happens to be a seat of the disease. The skin assumes a rough and brawny texture, which is more easily detected by touch than by sight.

Prurigo, though not strictly congenital, appears first at a very early age. The early form of the eruption is very often like that of lichen urticatus; at other times it closely resembles a papular eczema. As, however, age advances, the distinctive characters of the disease become more marked. The malady is generally worse in the winter than in the summer, and in a severe form is almost incurable.

In addition to the above-described prurigo of the young, we also meet with a spurious form of the malady which first shows itself in old age, and is commonly known as *prurigo senilis*. The eruption in this case is greatly aggravated, if not entirely produced, by the scratching of the patient.

DIAGNOSIS.—The word 'prurigo' is sometimes colloquially misapplied when simple pruritus is meant; thus we often hear the expression 'prurigo senilis' used when no eruption is present. These cases are generally either examples of chronic urticaria or of senile changes in the cutaneous nerves, leading to excessive and persistent itching. For the reasons already indicated, prurigo is more often mistaken for severe congenital eczema than for any other disease. Careful examination, however, of those parts of the body which have not been much scratched, together with the distribution of the eruption, will generally lead to a correct diagnosis. The malady may also be mistaken for scabies or

phthiriasis, but in both these diseases the parasite can be detected, and in scabies the distribution of the eruption and the history of the case are quite different from those of prurigo.

TREATMENT.—As has already been stated, prurigo, in a severe form, is incurable, but rest in bed for a few weeks always has a markedly beneficial effect. The itching may be greatly relieved by warm borax- and soda-baths, followed by the inunction of carbolised oil, or some similar application. Sometimes a very weak sulphur ointment is useful in relieving the itching; also a weak ichthyol ointment. Internal remedies do not appear to be of much value. It is necessary to treat the eczema which is so frequently associated with the disease. See ECZEMA.

ROBERT LIVEING.

PRURITUS (*prurio*, I itch).—A peculiar disturbance of sensation arising in the skin and in certain mucous membranes characterised by itching and giving rise to a desire, which may become uncontrollable, to stimulate the affected surface by scratching.

Pruritus may be produced by certain well-recognised forms of irritation; thus the stimulation produced by a fly moving on the skin or the application of a feather may cause temporary pruritus. In such cases the stimulation of certain sensory nerve-terminals appears plainly to be the cause; and the areas of the body in which pruritus is most easily excited do not necessarily coincide with those in which tactile sensation is most highly developed. In many forms of disease of the skin with local manifestations, pruritus is a prominent symptom. In some of these an efficient source of irritation of the sensory nerves is obviously present. Thus, in the disease especially named the 'itch,' the presence of the *Acarus scabiei*, its products, and the resulting inflammatory exudation furnish an adequate cause. The same may be affirmed of pediculosis. In many other diseased conditions such as urticaria, the lichenoid eruption remaining as the result of urticaria, and lichen planus, the exudation and the material concerned in its production may bring about the required stimulation. In other forms of disease of the skin, morbid changes, widely diffused, may produce a similar result, as in cases of general eczema and pityriasis rubra. It is noteworthy that diseases producing clinically similar lesions may not necessarily cause the same degree of pruritus, while in some cases the symptom of pruritus may be entirely absent. Thus, syphilis, producing an outburst of papular lesions, is usually devoid of pruritus, and the same may be said of certain forms of cutaneous tuberculosis and other granulomata. It may be imagined that the infiltration in such cases destroys the nerve-terminals in the cutis and in the epidermis. Pruritus appears to be an occasional result of the changes characteristic of senile degeneration of the skin. In so-called 'pruritus senilis,' the possibility of pediculosis and certain other conditions must always be carefully considered, but there can be little doubt that the degenerative changes, the rupture and disappearance of the elastic-tissue fibres and concomitant changes in the connective-tissue structures of the skin may produce severe pruritus.

The rubbing and scratching which are the instinctive consequences of pruritus produce in their turn secondary changes in the skin of the nature of

lichenification and eczematization, whereby renewed stimulation of the sensory nerves is produced, the vicious circle is completed, and the pruritus, instead of being temporary, becomes permanent. In addition, it appears to be the case that the habit of pruritus, or at any rate of scratching, may be induced. By the concurrence of these causes certain forms of disease with almost specific features originate. It is probable that at any rate some of the cases of prurigo arise in this way; and also some of the forms of pruritus genitalium, ani, scroti, vulvæ, &c. In this group of diseases the secondary changes are so severe, the cutis becomes so altered in structure as the result of œdema, vascular engorgement and cellular infiltration, the epithelium is so much destroyed or atrophied, that the disease becomes permanent and incurable.

Pruritus of varying degree and often general in distribution, is well known to originate as the consequence of disease of internal viscera. Thus the pruritus associated with disturbances of the liver, causing chœmia and jaundice, is familiar. It is not an uncommon feature in disease of the kidney, and is possibly most severe and trying to the patient in certain of the forms of glycosuria. The last mentioned disease is, unfortunately, specially liable to be accompanied by pruritus genitalium. Certain diseases of the nervous system are also accompanied by pruritus, when mental symptoms are present, especially in conditions of mental depression. The pruritus is occasionally of special type; it may be specially localised, and the condition known as 'formication' (p. 557) may be a feature. Pruritus of various types may occasionally be produced as the consequence of the taking of certain drugs, such as opium. Changes in temperature have a distinct influence on pruritus: occasionally cold has the effect of moderating the sensation, at other times the local application of heat soothes an attack. As a rule pruritus becomes worse when the vessels of the skin are dilated, as soon after going to bed. The changes of temperature in summer and winter have a peculiar effect in certain persons, producing what is known as *pruritus æstivalis*, and *pruritus hiemalis*, forms of the affection with very peculiar features.

TREATMENT.—The treatment consists, in the first instance, of removing all appreciable causes of irritation of the skin. The cure of scabies or pediculosis, if present, must be undertaken, and it should be remarked that many obscure cases of pruritus depend upon unrecognised scabies or pediculosis vestimentorum, pubis, &c. Equally clearly the treatment of such conditions as urticaria, eczema, lichen planus, when present, underlies the cure of pruritus. A disease which has much to do with the causation of the localised varieties of pruritus, such as the pruritus genitalium, is seborrhœa and the dermatitis associated with it. This condition should never be neglected, and frequently antiseborrhœic remedies will be the most effective way of relieving pruritus. As glycosuria is the most common of the general conditions producing pruritus, a careful examination of the urine for sugar should always be undertaken, and if found, treatment on antidiabetic lines is often very successful. Appropriate treatment must also be adopted in cases where the pruritus is associated with hepatic disturbances, dyspepsia, or Bright's disease. Of local remedies in cases of general pruritus, by far the most useful are simple or medicated baths. Warm baths, bran-

baths, and alkaline baths, are all of great service, and in other cases the bath may be medicated by the addition of the liquor picis carbonis, the oleum betule albae, or other antipruritic volatile oils or oleo-resins. A soap containing balsam of peru, camphor, and sulphur (of each 5 per cent.) is often of great service, used with the bath. After the bath the skin should be dried very gently, and the surface must not be allowed to cool rapidly or to feel chilled. The use of a simple dusting powder is agreeable, and the patient should rest as long as is possible. The application of lotions externally is very useful in the treatment of pruritus. Of the antipruritic remedies so used, carbolic acid is one of the best, and may be applied in the strength of 1 in 40 or 1 in 80 with the addition of glycerine (10 per cent. to 50 per cent.); perchloride of mercury (1 : 1,000, or 1 : 2,000), and the liquor picis carbonis are all of service. Such remedies also as menthol, thymol, camphor and chloral hydrate (equal parts rubbed together till liquefied) are of much service, and may be applied with care, or added to starch-powder in various dilutions and dusted on the surface. In cases of *pruritus genitalium*, the application of strong solutions of subacetate of lead, of nitrate of silver (1 per cent. to 4 per cent.) in water, and the compound tincture of benzoin have all been found of service. Ointments containing mercury, sulphur or carbolic acid are frequently of great service applied to the parts in pruritus of the perineum. The local application of water as hot as it can be borne to the scrotum or vulva frequently gives temporary relief. See ECZEMA.

Internal remedies in the treatment of pruritus should be avoided if possible, or used with caution, so as to avoid establishing a habit of taking drugs and the well-known evil results. The drugs found to be of most service are Cannabis Indica, opium and its alkaloids, and cocaine. Good effects have also been obtained by the use of nerve-depressants such as phenazone and acetanilide.

JAMES GALLOWAY.

PRUSSIC ACID, Poisoning by.—SYNON. : Fr. *Empoisonnement par l'Acide Cyanhydrique*; Ger. *Cyanwasserstoffsäurevergiftung*.

Prussic or hydrocyanic acid is one of the best known and most deadly of poisons. In the anhydrous condition it is stated to kill with almost lightning-like rapidity. Prussic acid is met with in commerce only in a diluted state. In this country two strengths of prussic acid are usual, the Pharmacopoeial acid containing 2 per cent., and the so-called Scheele's acid containing about 4 per cent., of anhydrous prussic acid in aqueous solution. The soluble cyanides, more especially cyanide of potassium, largely used by photographers and by electroplaters, are common articles of commerce, and produce the same deadly results as the acid itself. The fatal dose of prussic acid is the equivalent of less than one grain of the anhydrous acid.

ANATOMICAL CHARACTERS.—In persons who have died of prussic-acid poisoning, the eyes are glistening; the extremities are blue; the face is pale or livid; and the lips are cyanosed. The blood throughout the body has frequently the peculiar odour of the acid, and is of a dull hue, with a peculiar bluish cast—a glimmering appearance. The stomach is sometimes reddened, but not more than is common after other asphyxial modes of death.

SYMPTOMS.—In fatal doses the symptoms of prussic-acid poisoning set in very speedily; and in consequence of the readiness with which this poison is absorbed from the alimentary canal, and diffused throughout the circulation, the onset of symptoms is reckoned by seconds rather than by minutes. Occasionally the patient may be able to walk into an adjoining room, to compose himself in bed, or perform like actions; but it is rarely that he will have time to dispose of the cup, glass, or bottle in which the poison was contained, before he is taken seriously ill. The symptoms may be divided into three stages. The *first stage* is very brief, and manifests itself by difficult respiration, slow cardiac action, with a tendency of the heart to stop in diastole, while its beats are irregular. There is disturbed cerebration, and an awe-stricken aspect of countenance. This preliminary stage speedily ushers in the *second or convulsive stage*, the onset of which is occasionally signalled by a piercing shriek, though this is less frequently observed in man than in animals. With widely dilated pupils, the patient is suddenly thrown into violent clonic and tonic convulsions. The respiration is marked by shortness of inspiration, and prolonged efforts at expiration. The countenance becomes cyanotic. Vomiting is commonly observed; and the urine, faeces, and even semen in the male are spasmodically evacuated. The patient now sinks down, probably in a state of unconsciousness, and with complete loss of muscular power. The convulsive stage speedily passes into the *third*, or, as it may be termed, *asphyxial stage*, with slow, gasping, stertorous respiration, extreme collapse, loss of pulse, and more or less complete paralysis of motion. The skin is cold, clammy, and cyanosed. Death may be ushered in with irregular spasms. The onset of symptoms being rarely delayed beyond one or two minutes, death may occur within two or three minutes more. Power of volition is rarely continued in fatal cases for more than two minutes after taking the poison. Fifteen minutes is the longest interval which has been known to elapse between the taking of the poison and the commencement of symptoms; and then the patient recovered. Should the patient survive for thirty minutes, good hopes may be entertained of recovery. The longest period which is known to have elapsed between the taking of the poison and death was one hour and a quarter.

DIAGNOSIS.—This is rarely difficult. The *four-drayant* character of the illness, and the usually speedy death of the patient, coupled with the peculiar odour of the acid, and the finding of a cup or glass containing the remnants of the dose, seldom leave any doubt as to the nature of the case. Nitro-benzol poisoning closely simulates prussic-acid poisoning, however, except that the onset of symptoms is generally much later in nitro-benzol poisoning than when prussic acid has been taken. Nevertheless, when crude bitter-almond oil, impure from the presence of prussic acid, has been swallowed, the close similarity between the odour of the oil and that of nitro-benzol may lead to error. Fortunately, the same treatment may be adopted in both cases.

PROGNOSIS.—This in all cases is very doubtful; and no general rules can be laid down.

TREATMENT.—Prompt inhalation of the fumes of ammonia should, if possible, never be neglected. The successive administration of a solution of the

mixed per- and proto-salts of iron, followed by an alkaline carbonate, so as to convert the acid into an inert ferrocyanide, has been recommended on purely chemical grounds. There is, however, seldom or never time to admit of this elaborate treatment. A more practicable mode is to treat the patient with alternate douches of warm (115° F.) and cold water, so as to stimulate the respiratory functions; artificial respiration may also be employed, together with friction of the limbs. An emetic should be administered. A hypodermic injection of twenty minims of a 5 to 10 per cent. solution of sodium thiosulphate ('hypo'), or a few minims of solution of hydrogen peroxide may be employed. Faradic currents of electricity to the cardiac region should not be neglected. Atropine is not, as has been asserted, a true physiological antidote to prussic acid; but, injected subcutaneously, it may be of use as a respiratory stimulant. In spite of all treatment, the patient usually succumbs.

THOMAS STEVENSON.

PSAMMOMA (ψάμμος, sand).—A meningeal fibroma containing calcareous masses arranged in concentric laminæ. See CONCRETIONS.

PSEUDO- (ψευδής, false).—This is used as a prefix to various names of conditions, and signifies that they simulate certain diseases or conditions for which in their real nature they differ essentially; for example, *pseudo-angina*, *pseudo-asthma*, and *pseudo-cystis*.

PSEUDO-BULBAR PARALYSIS.—See LABIO-GLOSSO-LARYNGEAL PARALYSIS.

PSEUDO-CYESIS (ψευδής, false; and κύσις, pregnancy).—A synonym for spurious pregnancy. See PREGNANCY, Diseases and Disorders of.

PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.—See MYOPATHY.

PSEUDO-TABES.—A term, signifying false tabes or locomotor ataxy, which was formerly given to certain forms of multiple neuritis occurring more especially after poisoning by alcohol, arsenic, or as a sequel of diphtheria; in which the paralytic symptoms are generally slight, but where the muscular sense and other modes of sensibility are more or less involved, with the result of producing an ataxic condition of the limbs. See NEURITIS, MULTIPLE.

PSILOISIS (ψιλός, bare).—SYNON.: *Psilosis Lingue et Mucosæ Intestini*; Popularly known in the East as 'Sprue,' a word used by the Dutch and Lowland Scotch, which has reference to the symptoms in the mouth.

DEFINITION.—A chronic disease of the digestive tract, occurring, so far as is known, only in certain parts of Asia and the West Indies; unattended by fever; the most marked symptoms being diarrhœa, rawness and soreness of the tongue and throat, with a disposition to superficial ulcerations of the buccal mucous membrane, the presence of dyspeptic symptoms of various kinds, the passage of characteristic frothy, yellowish, or greyish-yellow, pul-taceous stools, progressive debility and emaciation; and, in unfavourable cases, terminating in death from atrophy and exhaustion; the disease in such cases usually lasting over several years.

ÆTIOLOGY.—The disease is climatic. Cases occur in Ceylon, the Straits Settlements, Indo-China, Java, Manila, and apparently the whole coast of China, more particularly the south. It is more rarely met with in the West Indies and Japan. The cause is unknown, but the probability of a bacterial origin is considerable. In one case the writer found that a particular rod-shaped bacterium prevailed in the motions in numbers over the other organisms in proportion as the disease was aggravated; and in cultivation-experiments this organism liquefied the gelatine with great rapidity. In two other cases under the writer's care, Wethered found a similar-shaped bacterium present in almost pure cultivations in enormous quantities.

ANATOMICAL CHARACTERS.—In fatal cases the small intestine is thin, shining, and translucent; generally in a condition recognised as atrophic, and lined by a covering of mucoid material which gives to the gut a peculiar velvety feel when handled, as though there had been some thickening of the coats, which, however, does not occur. In one case of the writer's the stomach, duodenum, upper part of jejunum, and large intestine were found practically healthy. The tongue was found to be denuded of its epithelium in certain circumscribed parts. The whole of the œsophagus was extensively diseased, the lining and glandular epithelium of the tube being entirely destroyed, and the surface formed by the bare submucosa. In the lower part of the jejunum there was slight inflammatory exudation around Lieberkühn's crypts, with a little destruction of the follicles at some parts. In the ileum the mucosa was almost entirely destroyed, its place being taken by a soft structureless substance. The submucosa was thickened, and contained an abundance of fibrous tissue of a solid character. The coats of the blood-vessels were thickened—a condition of sclerosis (Wethered).

SYMPTOMS.—The symptom to which the patient's attention is most directed is the occurrence of diarrhœa, which varies, however, very greatly in different cases. Sometimes it begins insidiously, the one irregular loose motion in the morning scarcely attracting attention, and it might be overlooked entirely if it were not for other symptoms associated with it, such as griping and general uneasiness. In other cases the diarrhœa is more marked from the beginning, the patient having several loose motions during the early morning without any further diarrhœa until the following day. There are cases, on the other hand, of which the writer has observed some well-marked examples, in which the disease begins with a sudden acute diarrhœa which lasts unchecked by remedies, within a short time other characteristic symptoms being observed. The extent of diarrhœa frequently bears no proportion to the other symptoms, being sometimes comparatively slight in otherwise well-marked cases. The motions are characteristic. At the outset they may consist of a copious discharge of a pale straw-coloured yellowish fluid, which is passed especially in the early morning, causing considerable weakness. During the day this diarrhœa ceases, the patient feels gradually stronger as the day advances, and towards the afternoon he usually feels quite well. In this way he may neglect his condition entirely for a period of many months, during which time he is gradually but steadily losing strength and weight. Sooner or later, but sometimes at the beginning, the motion is more

characteristic of the disease, consisting of the discharge of large quantities of a pulraceous mass, frequently of a putty or slate colour, sometimes pale yellow, sometimes brown. During periods of aggravation this large pulraceous discharge may contain an admixture of minute thread-like portions of a whitish substance. The motions have always a tendency to be frothy. When they consist of the abundant putty-coloured pulraceous mass, the frothy appearance is seen, the surface being often found covered with air-bubbles of various sizes, as if a process of active fermentation were going on. Stools of this latter quality are characteristic of the fully-developed stage of the disease. In cases that do badly, the motions, during this stage, may vary considerably from time to time, sometimes being of a watery or a dirty brown colour, and at other times of a light yellow, with intervals of the return of the pulraceous stool, which is found to contain, if carefully examined, portions of whatever food the patient is taking passed quite unchanged. Even when allowance is made for the large quantity of watery discharge in the motions, the quantity passed is out of proportion to the amount of nourishment taken, showing habitual deficiency of absorption in the intestine.

Early in the disease, and simultaneously with the disordered condition of the bowels, the patient's mouth usually becomes tender. At first there may be simply intolerance of hot food (as regards temperature), or of hot condiments, or of alcoholic drinks. Pepper, sherry, &c., burn his mouth, the tongue particularly. At the same time the tip of the tongue is felt to be tender when pressed against the teeth, and this tenderness may lead to a slight defect of articulation. In the early stages the tongue may be observed to be covered with a shining white fur, which being defective at certain parts shows patches of a bright red; the tip particularly, as well as the sides, being of a bright rosy red colour, while the under surface is seen to be redder than usual, and frequently with the redness accentuated at certain spots. As the disease progresses the fur gradually disappears, large papillæ being prominent for a time. While this process is going on, there may develop on any part of the tongue, but more usually on and under the tip and at the sides, characteristic superficial ulcers, which, while they destroy the investing epithelium, do not extend into the subjacent tissue. These painful superficial ulcerations may vary in size from a pin's head to a threepenny piece, or may be even larger, the larger ones being usually found in the mucous membrane of the cheek. The gums may become swollen, tender, and prone to bleed. Sometimes one solitary ulcerated patch may exist on the mucous membrane of the cheek or lip. Eventually the fur completely disappears from the tongue, which becomes apparently entirely denuded of epithelium, no papillæ being visible, and the whole surface presenting a dull red colour, more or less traversed by longitudinal and transverse furrows, the portions between these furrows being smooth. In some cases, in the advanced disease the tongue is very red, dry, glazed, and shining, and may or may not present cracks and crevices. There are rare cases in which the affection of the tongue is almost the only symptom present, there being no marked symptoms of diarrhoea, although the motion when examined will be found to be slightly altered in colour or consistence.

The patient in these cases complains bitterly of the irritability of the mouth and soreness of the tongue, but does not otherwise feel especially distressed. The extreme anæmia which sometimes becomes a prominent symptom produces a peculiar appearance in the tongue, the part towards the tip being of a pale tallow-like colour. At this stage the mucous membrane of the cheeks, lips, and palate (where not the seat of superficial ulceration) is of a dull, very pale yellow colour.

In a case of the writer's, the number of red corpuscles was reduced to 2,000,000 per c.m., the proportion of white corpuscles to red being 1 in 160. There was 68 per cent. of hæmoglobin. After a month of milk-diet the red corpuscles had increased to 3,580,000 per c.m., the proportion of white corpuscles to red being 1 in 190, while the hæmoglobin was 65 per cent.

The rawness is not always confined to the tongue. The passage of hot food or drink may be painfully felt in the whole course of the gullet, the tender condition of this tube sometimes rendering the swallowing of solid morsels extremely painful and difficult, and giving rise to prolonged and painful hawking, coughing, and sometimes vomiting. This condition occasionally develops early, and may be out of all proportion to the other symptoms, the patient sometimes requiring to get up five or six times during the night to rinse his mouth with water in order to relieve the dry hot sensation from which he suffers.

At an early stage of the disease dyspeptic symptoms develop, and sometimes give rise to much distress, the patient being troubled with flatulence, heartburn, and sour eructations. He suffers from a capricious appetite, sometimes characterised by a craving for meat. After the disease has lasted some time and when the will is weakened from the progressive debility, frequently he cannot be restrained from indulging in various kinds of highly indigestible foods, which are found in the stools absolutely unchanged, and which increase his sufferings and weakness by exciting considerable diarrhoea.

The mental condition of the patient is noteworthy. He is irritable, frequently depressed, and towards the later stages of the disease often extremely difficult to manage, refusing to acknowledge the gravity of his condition, and insisting on indulgence in foods which he cannot digest.

COURSE AND TERMINATIONS.—The disease is essentially a chronic one, being unattended by fever. The urine is usually free from albumen. The liver gradually shrinks in size, and eventually it becomes very small; but there is no reason to believe that this organ is primarily at fault. Such *post-mortem* evidence as has been obtained negatives the idea that the frequent paleness of the motions is due to any affection of the liver.

The abdomen, except at the beginning and the end of the disease, is usually tumid, bulging in the epigastrium, tympanitic, giving a soft doughy feeling to the touch; the tumidity being more noticeable as the patient progressively emaciates. The disease, which may last for a period of years, is attended by general atrophy and anæmia, the subcutaneous fat gradually disappearing till the patient reaches an extreme stage of emaciation, which, combined with the projecting eyes, pearly conjunctiva, and extreme pallor, gives rise to a peculiar and characteristic appearance. In the later

stages, and while recovery is still possible, there may be considerable oedema of the legs, with a rough harsh skin. In fatal cases the patient usually sinks with great slowness, death being mainly brought about by his being essentially starved to death, the processes of digestion and absorption having been for a considerable time almost entirely annihilated. Shortly before death blood and mucus may be found in the stools, attended by considerable pain in the rectum.

DIAGNOSIS.—This disease might possibly be mistaken for dysentery by the inexperienced, and is apt to be confounded with various forms of diarrhoea which are common in the tropics. In chronic dysentery, the mucus in the stools, the evidence of local irritation in the colon, inclination to strain, and the previous history of the attack, together with the absence of the characteristic symptoms of psilosis, ought to be sufficient to prevent any confusion between the two diseases. At the beginning of the malady it might be difficult to distinguish psilosis from other forms of diarrhoea, but after a time the condition of the tongue, mouth, and gullet, and the characteristic pulaceous stools which have been described, ought to be sufficient to establish the diagnosis. In simple diarrhoea of the tropics there are not present the peculiar local changes in the epithelium of the tongue and mucous membrane of the mouth, nor are the symptoms in the gullet present which are characteristic of psilosis; and those who are experienced in both affections should have little difficulty in distinguishing the frothy pulaceous masses of the latter disease. The peculiar changes in the mouth and throat are typical and distinctive. In the last stages of psilosis and of prolonged tropical diarrhoea the symptoms of exhaustion and emaciation are much the same; and in chronic exhausting diarrhoea the tongue may become bare and raw, with the formation of numerous aphthous spots in the mouth, which still further tends to obliterate the lines of distinction between the diseases in the fatal stages. In such cases it is necessary to take into account the previous history of the case.

PROGNOSIS.—Psilosis is always a grave disease, its gravity increasing in proportion to the age of the patient. In the earlier stages it is very difficult to get the sufferer to realise the serious nature of his malady. Patients under forty, who are willing to undergo the self-denial of suitable treatment, will probably recover, particularly if they remove to a temperate climate; but relapses are apt to occur for one or two years after recovery is apparently complete, particularly if the patient returns to a country where the disease is endemic. In patients who are middle-aged, and particularly in those who are over fifty, the gravity of the disease is much increased; but even at this age, if the constitution has been naturally strong, permanent recovery may take place even in cases in which the disease has lasted a considerable period. In all cases, even the slightest, it is advisable to point out to the patient and his friends that the seriousness of the case is out of proportion to the mere amount of diarrhoea present.

TREATMENT.—The treatment which has been found on empirical grounds to answer best is in accordance with what has been recently ascertained in connection with the morbid condition of the small intestine. The object is to give the weakened bowel (ileum) as complete rest as possible. The patient should be instructed to keep his bed for

several weeks, after which period the probable improvement of the symptoms usually permits his spending part of the day on the sofa or in an easy chair; but experience has shown that there is great advantage in maintaining the recumbent posture for some time. The abdomen should be covered with a thin layer of cotton wool kept in place by a flannel bandage, and the patient at once put on an exclusive milk-diet. The milk should be sipped slowly, must be pure and fresh, and should be slightly warmed. It is given in half-pint doses at regular intervals from 7 A.M. until 10 P.M. A small person will do very well with four pints daily, which is about the minimum quantity; but the usual quantity to begin with is five or five and a half pints. Should the patient be unable to take half a pint at once, a smaller amount should be given, and the intervals between each shortened, so that he may still take the desired quantity each day. The milk may be boiled, if wished, and some patients prefer it aerated; the aeration being effected in a gasogene or by 'sparklets,' and not by dilution with aerated waters. When the patient is unable to take a sufficient quantity of milk to increase his strength it is useful to have the amount of fluid reduced by evaporation. This is done by warming the milk in a 'Bain Marie' until it is reduced to half its original bulk. It must not be allowed to boil, and requires to be constantly stirred, both during the process of evaporation and until it has cooled. In favourable cases the improvement begins to be evident within a few days; the soreness disappears from the mouth; the motions become gradually more consistent, until eventually they become solid, the colour remaining for some time white and creamy-looking. It has been shown by the writer that this whiteness of the motions, which may continue over long periods during convalescence, is not due to absence of bile. When the motions become solid, the quantity of milk is gradually increased until, in an adult, eight pints or even more are given. After a few weeks there is usually considerable constipation, giving rise to pain and soreness, and frequently necessitating the use of an enema. At this period rhagades are apt to form at the anus, and may require to be touched with nitrate of silver. After the bowels have remained regular for five or six weeks, gradual additions are made to the diet; but here we find much difference in the idiosyncrasies of individual patients. A small quantity of bread is first allowed, beginning with two ounces daily, and if that produces no symptoms the amount is gradually increased to eight or nine ounces per day. If this is well borne the patient may be tried cautiously with boiled white fish—whiting, haddock, or sole. The next change in diet should be a few ounces of chicken or partridge, and after some days this may be alternated with boiled mutton, after which time cauliflower may be tried, and light farinaceous puddings in place of part of the bread. About the same time that fish is given fruit may be tried, bananas or grapes, the skins and seeds being rejected. The writer has had cases in which large quantities of strawberries could be taken with milk, when other additions to the milk disagreed, and in consequence more milk could be taken and rapid improvement of the patient took place. In connection with all added articles of food, it is important to bear in mind that any one of them may in some patients cause a relapse of the symptoms. When this occurs the

patient should be at once put back on milk-diet, and kept on it for four or five days, when the additions to diet may be again begun, this time avoiding the particular article of food that had been found to disagree. The writer has known relapses produced by eggs (which are usually well borne) after recovery had begun. Although fish generally agrees well, he has known a relapse brought on by boiled whiting, and so on with almost every article of food he has tried, with the exception of milk. Unfortunately, there are cases, although very rare, in which milk cannot be borne, and indeed seems to aggravate the symptoms, in which case raw-beef juice may be tried, and to obtain it in sufficient quantity the juice of twelve to twenty pounds of beef daily is required. In order to express the juice it is necessary to use one of the machines specially made for the purpose.

In some cases there is such an intolerance of starchy foods that after the motions have been solid on milk-diet for five or six weeks, an ounce of bread per day will reproduce the diarrhoea. In these cases very finely minced rump-steak is sometimes well borne, taken raw or very lightly cooked. It is best to begin it without any other addition, the diet then consisting of milk and two ounces of the minced beef daily. If this agrees, two ounces may be given twice daily, and after a time it may be tried as a sandwich between very thin slices of bread, and by this time it will generally be found that the bread does not disagree, the patient having become much stronger in the interval.

In cases in which recovery from the disease has been incomplete, and a tendency to frequent relapses is left, a meat-diet on the principle of the 'Salisbury' treatment often answers. The milk-diet is abandoned; and finely minced, very lightly cooked meat is given three times a day, combined with a small quantity of farinaceous food. If this treatment is well borne, as it often is, the tendency to diarrhoea disappears, the patient becomes stronger, and after a time—sometimes a comparatively short time—his diet may be varied without inconvenience.

On account of the tendency to relapse, the patients require to be encouraged and reassured, as in well-managed cases the relapses usually do not last more than four or five days. When the patient has been able to digest solid food, and there is no return of the distinctive symptoms, he should be allowed to go out; but he must for a long time avoid fatigue. A chill will at any time, for months after he has apparently recovered, produce a relapse. Drugs have no effect on the disease, although a slight temporary improvement may sometimes be seen after the exhibition of a small dose of rhubarb. For a severe diarrhoea with pain, which occurs occasionally, particularly in the relapses, a moderate dose of laudanum is useful, but opium has no curative effect on the malady. The patient should not return to the country where the disease occurs if he can avoid doing so, as experience shows that relapses are common in these circumstances. Where the return is unavoidable, if possible a whole year should be allowed to elapse after complete recovery, before leaving again for the East. Patients who remain at home, and who have made a good recovery, usually remain well; and many patients who have been under the writer's observation, and who at one time suffered severely, now enjoy perfect health, and follow their ordinary occupations.

G. THIN.

PSOAS ABSCESS.—SYNON.: Fr. *Abscès du Psoas*; Ger. *Psoasabscess*.

DEFINITION.—An abscess within the sheath of the psoas muscle, almost always of spinal origin.

ÆTIOLOGY.—Caries of the lower dorsal or lumbar spine is the cause of psoas abscess, and these being the regions of the spine most commonly diseased, this is the commonest form of spinal abscess. The caries is almost always tubercular. Syphilis and actinomycosis are rare causes. Rarely, too, an abscess starting from the hip-joint makes its way into the sheath of the psoas, and travels upwards in it, even to a lumbar transverse process, as the writer has seen in a case of pyæmic suppuration in both hip-joints. It is said that a suppurative inflammation may arise within the psoas sheath, unconnected with disease of bone or joint, but supposed to be consequent upon strain or exposure to cold.

ANATOMICAL CHARACTERS.—The disease may begin on the surface of one or two vertebræ; a tubercular periostitis results and generally spreads over several bodies (*anterior caries, caries without curvature*), a form occurring chiefly in adults, specially liable to end in abscess, and formerly regarded as exceptionally fatal. An abscess from such a source lifts up the anterior common ligament, and all structures in front of it, such as vessels, pillars of the diaphragm, and so forth; these become matted together in dense fibrous tissue, and form the anterior wall of the abscess cavity. More commonly the disease appears in the body of one or two vertebræ close to an intervertebral disc, because, as is supposed, it is here, at the junction of bone and cartilage, that the slight injuries which so often precede and predispose to tubercular disease take effect. The result of the settlement of bacilli is the formation round about them of an inflammatory infiltration, which may be small and circumscribed, or, more rarely, diffused throughout the body of the vertebra as a general osteitis. In either case, as a rule, it tends to spread, making its way towards the surface, usually the antero-lateral: a periostitis is now excited. As the infiltration spreads it caseates and dies in its older portions. The infiltration ordinarily eats away the cancelli, and, under the influence of pressure, the part above the eroded area sinks down on to that below it, and a 'Pott's boss,' or projection of the spines, is thus produced. With a less acute infiltration sclerosis of bone results, and a subsequent exacerbation of the inflammation or caseation of the products will lead to the formation of considerable sequestra of dense bone. Smaller sequestra are frequent, and result from caseation of an infiltration which still contains particles of uneroded bone (*caries necrotica*). Having reached the surface and excited a periostitis, the disease may spread to neighbouring vertebræ, skipping over the discs, and destroying them by eating away the bone on each side of them rather than by direct attack; and as body after body is eroded the curvature increases. The disease may be arrested, and often is, under suitable treatment. But in many cases, especially among the poorer classes, and among adults in all classes, the caseous material 'softens,' i.e. becomes mixed up with a quantity of fluid in which the fatty cells and their *débris* float. This mixture constitutes the 'pus' of chronic abscesses; it is thin and watery, quite opaque, pale yellow-white, often contains visible and sometimes large masses of fattily degene-

rated cells, and bony and calcareous particles may be numerous when the abscess springs from bone. This fluid, as it increases, presses onwards in the direction of least resistance. Starting from the lower dorsal spine, it may pass through the diaphragm with the aorta, but much more commonly it extends laterally beneath the pleura so as to reach the highest digitation of the psoas rising from the lower edge of the twelfth dorsal vertebra. With this slip it passes beneath the internal arched ligament of the diaphragm, and thus enters the sheath of the psoas. Pus from lumbar vertebræ may enter the sheath at once, if the disease reaches the surface at a point from which one of the slips of the psoas arises; otherwise the subperiosteal abscess travels on the front of the spine and extends laterally until, perhaps, it raises one of these slips of origin from the bone and thus enters the sheath. The aperture of communication between the psoas sheath and the cavity in front of the diseased bone is often very small; there may be more than one. Having thus entered the sheath of the muscle, the pus by its constant pressure and irritation causes atrophy of the muscle-cells, and inflammation, which leads to thickening of the connective tissue into a capsule for the pus; this capsule is lined with a thick layer of very loosely adherent granulation-tissue, which, no doubt, adds its quota to the fluid and solid contents of the cavity. It is tubercular from the first, and cheesy points in it are numerous. Crossing the interior of the cavity are more or fewer bands, some containing vessels, others nerves of the lumbar plexus; pain or numbness, referred to their distribution, and wasting of special muscles are, therefore, not to be wondered at. Pressing on, the pus may so distend the psoas that it will reach out to the anterior iliac spine; but, usually, fluid as far out as this lies beneath the iliac fascia, with which the psoas fascia is continuous on its outer side. An abscess filling the iliac fossa and not passing beneath Poupart's ligament is called an 'iliac abscess'; it is a stage of a psoas abscess. But from the iliac fossa it is said that pus may pass out over the crest through Petit's triangle, which involves its bursting through the strong iliac fascia. This certainly takes place when the pus makes a way to the surface through the muscles of the abdominal wall just internal to the anterior iliac spine. Having or not having filled the iliac fossa, the pus usually passes down behind Poupart's ligament, lying external to the femoral artery; then, taking the profunda for its guide, it runs inwards behind the main vessels, over the pectineus and adductor brevis, between the adductors longus and magnus, to the inner side of the thigh. Rarely do we see an abscess of such extent nowadays; but formerly they occasionally ran down even to the internal malleolus. It is common for diverticula to pass from the cavity along branches of the profunda, especially along the internal circumflex, which conducts the pus to the face of the quadratus, and the swelling indicating it presents on the buttock beneath the lower fibres of the gluteus maximus. Besides this, there may be no other perceptible swelling in the thigh; it must not be mistaken for an abscess pointing through the great sacro-sciatic notch.

Pus from lumbar vertebræ may pass beneath an arch of origin of the psoas over the side of a vertebra; then, taking the lumbar artery and its posterior division as its guide, the pus runs back

internal to the inter-transverse ligament, and issues beneath the latissimus, having escaped from between the erector and quadratus. This is the 'lumbar abscess' of spinal disease. Rarely, pus from lumbar caries may run down along the great vessels into the pelvis. A pelvic spinal abscess is almost always of sacral origin.

SYMPTOMS.—At first the symptoms are those of spinal disease. If an abscess is forming quickly, and much tension within the muscle-sheath is developed, full extension of the hip causes pain, and persistent flexion is consequently maintained; but in less acute cases there is often no history of pain, lameness, or flexion. There may be pain along the line of one or more branches of the lumbar plexus. Even the ordinary symptoms of spinal disease are not very rarely absent, and a swelling in the groin is the first thing noticed. It often seems to have appeared suddenly; lies external, and perhaps also beneath and internal to the vessels; is smooth, rounded, more or less tense, and more or less fluctuant; is covered by normal skin; is not tender; has a distinct impulse on coughing; and may disappear more or less completely in the recumbent position or on pressure. Fluctuation is obtainable between a fulness above Poupart's ligament and the swelling below it. Though the former may be slight, it is generally considerable, and may actually distend the abdomen up to the ribs. Sooner or later, either above or below Poupart's ligament, the abscess points; the skin then reddens, thins, and finally gives way. This may take place with some acuteness.

DIAGNOSIS.—There is no difficulty when the abscess is typical, and spinal disease marked. But a swelling like an iliac or psoas abscess may be present without obvious spinal disease. The probability is that it is of spinal origin, and searching inquiry must be made for occasional pain in the back or in the stomach; for disinclination for active exercise (especially jumping), and early fatigue; for any tendency to use the arms to take off part of the weight of the body from the legs; and for slowness or difficulty in performing such movements as rising from the stooping or sitting posture. The spine should be carefully examined for any slight prominence; and, if any is found, percussion and heat must be employed here and may strengthen the suspicion excited.

The surgeon should cause the patient—stripped to the hips—to execute before him all the movements of the spine (bending forwards, backwards, and to each side, and rotation towards each side), and should note whether they are completely, sharply, and painlessly performed, and if all the spines seem to separate, or whether certain ones retain their distances, indicating that a length of spine is held fixed. But it is not always possible to establish a certain diagnosis, as cases in the writer's experience show.

Failing to find evidence of spinal disease, it becomes necessary to seek for other possible causes of psoas abscess; the hip-joint must be proved healthy, the renal region must be explored, the urinary history gone into, and the urine examined; the possibility of empyema pointing in the groin must be excluded; in case of iliac abscess, abscess from disease of the ilium or appendix vermiformis, abscesses following on pelvic peritonitis and parametritis, soft rapidly growing tumours and serous and hydatid cysts of the iliac fossa must be thought of.

PROGNOSIS.—Under modern antiseptic treatment the prognosis is relatively good. Its gravity increases, so far as the abscess is concerned, with the size and number of branches of the abscess, and with the age of the patient. The gravity of the case is greatly increased if the abscess cavity becomes septic; children are much more likely than adults to survive this complication.

TREATMENT.—A few cures may be ascribed to simple rest alone or with repeated aspiration. Usually these fail and aspiration often leads to a sinus probably by infection of the skin as the needle is withdrawn.

Here, as elsewhere, in dealing with tubercular disease, the object is to remove as much as possible of the tubercular tissue. This is best effected by careful scraping with a sharp spoon to detach the lining granulation-tissue from the whole surface. Incisions must be so placed—in loin, groin, thigh, and buttock—as to allow the spoon to reach every point of the surface. Either during the scraping, by means of a flushing curette, or afterwards by a suitable tube attached to a douche-can, all débris should be washed out of the cavity with warm sterile, normal saline solution. Then each opening should be closed—fascia to fascia, muscle to muscle, and skin to skin—after disinfection of the edges: the use of a small skin-flap to cover the deep wound is also helpful in preventing infection of the wound and formation of a sinus. It is a good plan to mix with the last pint of saline solution run into the cavity half to one drachm of powdered iodoform, which is thus deposited upon the walls. Often the cavity refills: tension should be warded off by aspiration through a fairly thick part of the wall, and this should be repeated as may be necessary. In successful cases, the fluid withdrawn is honey-like, smells of iodoform, and contains few or no caseous flakes and is formed more and more slowly. In failures, fresh curdy fluid is formed or ordinary pus, if pyococci have gained entry. In the former case scraping may be repeated; in the latter free antiseptic drainage is the proper course. Should a sinus form, it must be carefully guarded from sepsis. The spinal disease and the general health must be attended to. The danger of this treatment is slight: its advantages, when successful, very great.

A psoas or iliac abscess should be thus treated as soon as discovered. If not yet presenting in the groin, it should be opened in the loin through an incision passing outside the erector and through the quadratus on to the psoas.

STANLEY BOYD.

PSORIASIS (ψώρα, scurf).—**SYNON.** : Lepra; Alphas (both obsolete); Fr. *Psoriasis*; Ger. *Schuppenflechte*; *Psoriasis*.

DEFINITION.—A chronic inflammatory disease, occurring chiefly on the extensor aspect of the limbs, and consisting of discoid patches with scaly crusts on a red base.

VARIETIES.—There is really only one kind of psoriasis, but the older writers gave names to the different phases of the disease founded upon (1) the size of the patches, using such qualifying terms as punctata, guttata, nummulata; (2) the extent of the disease—diffusa, universalis; (3) the covering of the patches—rupioides, empyodes; (4) their shape—circinata, gyrata; (5) their duration—in-veterata, &c. Scaly syphilides also are often spoken of as syphilitic psoriasis, but modern derma-

tologists avoid all these artificial and ambiguous varieties, which are of no practical importance and in the case of the syphilides are misnomers.

ÆTIOLOGY.—Psoriasis attacks equally both sexes and all classes. It is rare before three years of age, though cases have occurred in early infancy, while it is very common in childhood and puberty, so that 70 per cent. have their first attack under thirty years of age and only 5 per cent. begin after fifty years, but those previously subject to it may go on having it up to any age. It is hereditary in a large number of cases, but not very strongly, as it is not often that more than one or two in a large family are affected. The general health is often quite good, but depressing influences, whether of mind or body, will often determine an attack in those predisposed to the disease. Gout and other arthritic conditions are predisposing factors in adult life, but only in a small proportion of cases. Spring and winter are the most common seasons for a new outbreak.

ANATOMICAL CHARACTERS.—The true pathology of psoriasis is still unknown, but the theory of a microbe which, perhaps starting in the skin, subsequently gets into the circulation and is distributed symmetrically, is consonant with the clinical facts. Unna's theory that it is part of the seborrhœic process is not accepted. The anatomical changes are those of moderate inflammation in the papillary layer of the corium, producing cell-infiltration and vascular dilatation, chiefly round the hair-follicles and sweat-ducts. The horny layers and those of the rete are enormously and rapidly increased, except over the papillæ, and there is a great tendency to premature cornification and exfoliation. The papillæ are much enlarged by the down-growth of the interpapillary processes. Some pathologists hold that the change in the rete and the premature conversion into horny cells are the primary conditions to which the inflammatory phenomena are secondary.

DESCRIPTION.—No part is absolutely exempt from attack, but the disease generally appears first and in its most typical aspect on the extensor surface of the limbs, especially the elbows and knees, and the parts below; and it is often confined to these regions, the flexor aspect being actually free or only affected in a minor degree. Next in order of frequency are the scalp, trunk, the back more than the front, the face comparatively seldom, but more frequently in women and children than in men, while the palms and soles are rarely attacked. The disease is in the main symmetrical in its distribution.

A well-developed patch, which may be from a half to two or three inches in diameter, is well defined at the border, contrasting sharply with the healthy skin, and consists of a brightly reddened disc more or less concealed by silvery scales adhering into a spongy crust. When this is removed, the under layer being generally firmly attached, bright red, easily bleeding points are brought into view, which are the tops of the enlarged papillæ. The amount of scalliness varies with the acuteness of the process. When slowly formed, the scales are closely adherent to each other and to the plaque, while in acute cases they flake off too quickly to form crusts, and the intensely hyperæmic base is freely exposed. On the back of the hands and the face the scales get washed off. On the scrotum the natural moisture has the same effect, and there is

often fissuring and great irritation. On the palms and soles, patches are seldom seen, but the epidermis is dry, thickened, and cracked, imparting a worm-eaten appearance to the part. In the scalp, the hair is dry, but seldom comes out much, except in acute cases. The nails are, however, often discoloured, pitted, furrowed, and brittle, and separated from their bed, beginning at the distal end at one side. In rare instances the mucous membranes have been slightly involved.

DEVELOPMENT AND COURSE.—Each lesion begins as a papule the size of a pin's head, surmounted almost from the first by a scaly cap; this speedily enlarges to a small disc, which continues to spread peripherally until a patch of two or three inches in diameter may be formed. Larger areas are produced by coalescence of adjoining patches; but, however extensive they may be, there are always some areas of healthy skin. When regression takes place it commences in the centre, and when this is clear a circle is formed, or, if the patches have previously coalesced, a gyrate contour. Occasionally, however, on the trunk gyrate and circinate patches are primarily formed from the disease attacking the hair-follicles only, and following therefore their arrangement; this is the lepra of Willan. As further absorption occurs the circular border is broken up, and ultimately the fragments also disappear, leaving a transitory red stain, or a long-lasting yellowish-brown one when the disease has been treated for some time with arsenic. Itching varies much: it may be absent, or very slight, but as a rule is present in a moderate degree, and is only rarely as intense as in eczema.

COMPLICATIONS AND SEQUELÆ.—Papillary development may occur on the patches, which may be soft and papillomatous or hard and warty. Deep and extensive pigmentation sometimes occurs without arsenic having been given. Scarring, keloid, and epithelioma rarely ensue, the latter developing either on a warty psoriasis, or on the warts left by excessive arsenical treatment.

DIAGNOSIS.—The characteristic features of psoriasis are the position of the patches chiefly on the extensor aspect of the limbs, and especially on the elbows and knees; the borders of the patches being well-defined; the scales being white and adherent into crusts, but without inflammatory exudation. When the crusts are removed, bright red, easily bleeding points are visible. The presence of all these features renders the diagnosis inevitable. Lichen planus, eczema, pityriasis rubra, tinea circinata, and squamous syphilides in some phases, are the diseases most likely to be mistaken for psoriasis.

The patches of lichen planus are roundish, well-defined, and scaly, but they do not choose the special seats of psoriasis; the scales are scanty compared with psoriasis; the colour is violet red instead of bright red. They leave deep pigmentation behind them, and there are almost always some of the characteristic flat papules in the neighbourhood of the patch. Scaly patches of eczema are seldom defined at the borders; the scales are in a single layer or mixed with inflammatory exudation, or there may be a history of discharge; there are no bright red points when the scales are removed; finally eczema is much more common on the flexor than the extensor surface of the limbs, and even on the extensor aspect does not specially choose the elbows and knees.

In pityriasis rubra, confusion could only arise before the disease became truly universal, and when the psoriasis is in an acutely inflammatory condition; then the base is intensely red, and the scales flake off easily and rapidly, so that no scaly crusts are formed. Pityriasis rubra is diffuse, not in patches; the border is less defined; the colour is an intense bright red; the scales are large, thin, and papery, do not conceal the ground-colour, never adhere into crusts nor over their whole surface, and are thrown off almost as rapidly as they are formed. It must be remembered that pityriasis rubra sometimes develops from a pre-existing psoriasis, but the change is usually acute, and there will be a history of previous chronic patches.

In tinea circinata, the small number of non-symmetrical patches coming in any part of the body, the very scanty scales and the at first papular border, ought to lead to microscopic examination of the scales for the fungus, if a positive conclusion cannot be arrived at without it.

Secondary scaly syphilides are rarely acquired before adult age, while psoriasis is a common disease of childhood; on the other hand, psoriasis is rare under three years, and does not therefore clash with congenital syphilides. The scaly syphilide is in small patches, with scanty, dirty-looking scales on a dull red base; does not specially affect the extensor aspect of the limbs; is often associated with other forms of eruption; leaves fawn-coloured pigmentation behind; and is nearly always accompanied by the other symptoms of syphilis. In the circinate scaly syphilide the same distinctions in position, colour, scales, and concomitant symptoms hold good. In the tertiary scaly syphilide the resemblance may be rather close, but position will again assist: the face is often affected; the number of patches is usually small; they are not symmetrically arranged; the edge is more raised, the centre more depressed; ulceration is common; and scarring and pigmentation follow the disappearance of the lesion.

PROGNOSIS.—It is always possible, but often difficult, to remove the lesions of any one attack, but recurrence at some time or other takes place in 90 per cent. of cases, the interval of freedom varying from weeks to years. Sometimes psoriasis disappears spontaneously, but more often continues for years with remissions and exacerbations, which may at any time assume a severe form with widespread distribution.

TREATMENT.—Combined external and internal treatment is the most rapidly efficacious method of removing the eruption of psoriasis, cases of moderate extent requiring from three weeks to three months. The short period assumes that the patient gives himself up to treatment and is in skilled hands. The general health being in a majority of cases undisturbed, specifics find their most fitting opportunity, of which arsenic, thyroid extract and salicin are the most important. The soundest principle, however, is to search carefully for any departure from the highest standard of health, and to endeavour to rectify it, if found, before resorting to the routine treatment with arsenic.

Conditions depressing vitality are the most common: overwork, anxiety, suckling, or any prolonged drain upon the system may be determining factors. Gout and rheumatism take a more subordinate place, but if present require appropriate

treatment; and only when these difficulties have been removed or met should specifics be called in.

Arsenic may be given in either a solid or liquid form; and although practitioners have their fancies for this or that salt, practically arsenious acid for pills, and Fowler's solution for mixtures, meet all requirements. The recently introduced cacodylate of sodium is a dangerous form on account of the large quantity of arsenious acid in it; half a grain three times a day is recommended, but is equal to ninety minims of Fowler's solution. One grain three times a day produced acute poisoning in one case.

The solid form is often the most convenient, as it interferes least with the patient's avocations. The following are useful formulæ: Arsenious acid one grain, liquorice powder \mathfrak{zj} , extract of hop \mathfrak{zj} ; mix thoroughly, and divide into 30 pills. Take one three times a day after meals. The well-known Asiatic pills are stronger, containing nearly $\frac{1}{12}$ of a grain of arsenic in each, and are much used abroad: Arsenious acid 66 grains, powdered black pepper \mathfrak{zix} ; gum arabic and water a sufficiency; mix and divide into 800 pills. Take one three times a day after meals. When the patient is tolerant, and the disease obstinate, the dose may be increased until the limit of his endurance is reached, griping and diarrhoea being obviated by combining opium; of course, the effect on the patient as well as on the disease should be watched. But while the pills will always hold a place on account of their convenience, where practicable, the *Liquor Arsenicalis* is preferable, as it can be freely diluted, and the irritant effect on the stomach is more likely to be avoided. Beginning with 3 to 5 minims, it may be pushed up to 10 or 12 minims or more, three times a day, always after meals.

Improvement is not manifested at once; often the full physiological effects of the drug must be reached before the scales cease to form; then the older ones drop off, the patch begins to clear, first in the centre and then gradually over its whole area. Arsenic is contra-indicated when the eruption is very hyperemic, or is coming out acutely, or when there is acute or chronic irritability of the alimentary canal. It will often make acute cases spread faster, and increase the itching very considerably. Even in suitable cases, however, this increased itching may also be excited at first; but it subsides in a week or two, and the patches begin to clear up.

It must not be supposed that even in apparently suitable cases arsenic is always successful. Unfortunately its failures are only too numerous, and it is a very disappointing drug. Moreover, if continued too long it produces a general pigmentation of the skin and a warty thickening of the palms and soles of a permanent character.

In a limited number of cases the administration of thyroid extract is followed by the removal of the eruption, and in a few cases in a remarkably short time. It should not be given to elderly persons or to those who have weak hearts, nor in cases where the psoriasis is coming out in fresh spots, or when the old patches are spreading. The dose should be a small one to begin with, 5 grains a day. At the end of a week the dose may be increased to 10 grains a day, and at the end of three weeks probably the dose again increased, provided that no symptoms of thyroidism, e.g. headache, giddiness, and rapid pulse, have appeared.

Larger doses are seldom advantageous and may be even dangerous.

Salicin and salicylate of sodium were introduced by the writer for psoriasis, and have the advantage over arsenic or thyroid of being useful even in spreading cases. Salicin is generally preferable to salicylate of sodium. The initial dose of salicin should be 15 grains three times daily, and it may be increased to 20 or even 30 grains. In a few cases it may disturb the digestive function or produce erythema. In most cases the hyperæmia rapidly diminishes, the scales are loosened and fall off, the patch clears in the centre, the scaly ring breaks up, and only small fragments are left which are best removed by local means.

The local treatment consists in removing the scales by alkaline baths or soft soap, and then rubbing in stimulating and antiseptic applications, in the form either of lotions, liniments, or ointments. The local applications may be placed in three divisions, in the grade of their stimulating effect, although that probably is not their sole mode of action, as they are all more or less antiseptic. In the first division may be placed the mercurial preparations, of which the ammonio-chloride, the nitrate, and the yellow oxide are chiefly employed; either may be used as an ointment, in the proportion of \mathfrak{zj} to the \mathfrak{zj} of lard or other base. They should not be used over a very large area, nor continuously, but be rubbed in night and morning. This applies to all stimulating methods of treatment. In the next division come the tarry preparations, naphthol, and thymol. Preparations of tar have long been the classical treatment for psoriasis. They are very numerous, but oil of cade and *oleum rusci pyroligneum* or birch-tar oil are the least objectionable for ointments or liniments, and are used in various strengths from \mathfrak{mxx} to \mathfrak{zjij} to \mathfrak{zj} , or even stronger. For a lotion the alcoholic solution called *liquor carbonis detergens*, from \mathfrak{zss} to \mathfrak{zjij} to \mathfrak{zviij} of water, sponged freely over three times a day, is often very useful. β -Naphthol, resorcin and thymol are generally used as ointments: \mathfrak{zj} to the \mathfrak{zj} is an average strength, the addition of \mathfrak{zj} of prepared chalk facilitating the preparation of the ointment. They have the advantage of being cleanly and free from disagreeable odour. In the third division are the strongest stimulants, such as turpentine, pyrogallic acid, and chrysarobin. Turpentine is used as a liniment from 1 to 4 up to equal parts of it and olive oil. Pyrogallic acid and chrysarobin may be used as ointments, gr. v to \mathfrak{zj} to the \mathfrak{zj} . Pyrogallic acid stains linen, and dangerous absorption may ensue if used over a large surface (p. 615). Chrysarobin also stains both skin, hair, and linen, and may excite an erythema with œdema resembling erysipelas (p. 422); it soon passes off when the drug is stopped. In suitable cases it is the most rapidly efficacious of all local remedies. Moreover, in small quantities such as 1 grain to 5 grains of Ung. Zinci its range of usefulness may be extended even to hyperæmic cases, and remarkably good results obtained with care and judgment. These are only a tithe of the remedies suggested for this obstinate disease, and they may be combined in endless variety and strength. The guide in the selection of a remedy is the amount of hyperæmia present in the patches. The more acute the process, the less stimulation is required; and if very acute, soothing applications, such as

simple olive oil, olive oil combined with calamine, oxide of zinc and lime water, or the glycerin of the subacetate of lead (1 part to 7 of distilled water) may be bandaged on continuously. The patient's circumstances and occupation, as well as the position of the eruption, are also to be taken into account in choosing the remedy and mode of applying it, and considerable experience is requisite to form a correct judgment on all these points.

H. RADCLIFFE CROCKER.

PSOROSPERMOSIS (Greek *ψώρα*, itch).—This term is applied to lesions in the human subject produced by certain forms of Protozoa (*Sporozoa*), allied to the *Coccidium oviforme* which affects the bile-ducts of rabbits. Sporozoa or psorosperms are unicellular organisms which multiply by fission; each of the primary fragments thus produced becomes surrounded by a firm coat and is known as a spore, the whole number of spores being contained in a capsule or cyst. Subsequently each spore may again divide into smaller bodies which ultimately develop into mature individuals. The whole cycle of development probably does not take place in one host.

In man the infection may either be generalised throughout the viscera (rare), or localised in the liver, urinary tract or the skin. In the liver definite tumours are formed which may even be palpable through the abdominal wall. In this situation the parasites give rise to symptoms of pain and indiges-

Three Psorosperms (two shown in section) from a Ureter. (Leitz, obj. $\frac{3}{8}$ in., Zeiss, oc. 2.) (After J. J. Clarke.)

tion, with fever, delirium and ultimately death. In the kidneys and ureters—a comparatively frequent seat of infection—the mucous membrane is found studded with minute cystic nodules, about 2 mm. in diameter, which may even block the ureter and cause hydronephrosis. Hematuria, anæmia and frequent micturition are the prominent features of the condition, and death occurs in a few weeks. In the skin, a spreading dermatitis is produced with nodular or vesicular lesions. When the infection is generalised the condition is comparable to trichinosis. The symptoms comprise pains in the limbs, vomiting, headache, delirium or drowsiness and irregular pyrexia. Death occurs generally in a fortnight or three weeks, the patient passing into a typhoid condition; occasionally the duration of the illness may be rather more prolonged. No treatment is known to influence the course of the infection. Diagnosis can only be made by the discovery of the typical cysts and parasites (see fig.). Psorosperms have been

described in Darier's disease (*Keratosis follicularis*) and in Paget's disease of the nipple; also in molluscum contagiosum and in carcinoma. It is most probable that the bodies taken for protozoa in these conditions are in most cases peculiar products of cellular degeneration. Plimmer and others have cultivated fungi allied to yeasts (*blastomycetes*) from carcinomata, and the same has been done in the disease peculiar to California, known as 'protozoic dermatitis,' which was originally ascribed to psorosperms. It is possible therefore that parasitic fungi have at times been classed as protozoa.

W. CECIL BOSANQUET.

PTOMAÏNES (πτῶμα, a dead body).—SYNON.: Cadaveric Alkaloids; Fr. *Ptomaines*. Ptomaines are alkaloids produced by the decomposition of animal substances. The word *ptomaine* was at first restricted to alkaloids produced by cadaveric decomposition, but it is now also employed to designate alkaloids of animal origin formed during life, as a result of chemical changes induced by some agency or other acting within the organism. The term *leucomaine* has been introduced to particularise the animal alkaloids formed during life from those produced by decomposition of dead animal matter; but it would be preferable for the terms *ptomaines* and *leucomaines* to be abandoned, and to class these bases of animal origin in one category as *animal alkaloids*.

It is now well known that the power of manufacturing alkaloids is not restricted to plants, but is shared by animal organisms.

Creatinine, discovered in urine by Liebig and Pettenkofer, was the first body of animal origin acknowledged to be an alkaloid.

Ptomaines of known composition.—The common ancestor of alkaloids, whether animal or vegetable, is albumen, the complex albumen-molecule being split up, either by bacterial agency or otherwise, into several less complex molecules, among which are the animal alkaloids. The following is a list of the principal ptomaines that have been extracted from putrefying animal matters, and submitted to ultimate analysis:—

Collodine, $C_8H_{11}N$, from putrefying horseflesh and mackerel.

Parvoline, $C_9H_{13}N$, from putrefying horseflesh and mackerel.

Unnamed base, $C_{10}H_{15}N$, from putrefying fibrin of bullock's blood.

Hydro-collodine, $C_8H_{13}N$, from putrefying horseflesh and mackerel.

Putrescine, $C_4H_{12}N_2$, from human corpses.

Neuridine, $C_5H_{11}N_2$, from human corpses, and from putrefying fish and cheese.

Cadaverine, $C_5H_{11}N_2$, from human corpses.

Neurine, $C_5H_{13}NO$, from cadaveric putrefaction.

Choline, $C_5H_{13}NO_2$, from cadaveric putrefaction.

Muscarine, $C_5H_{13}NO_2$, from putrid fish.

Gadinine, $C_7H_{16}NO_2$, from putrid cod-fish.

Tyrotaxonin (diazobenzene butyrate), from decomposing cheese, milk, and cream.

Animal alkaloids are also a necessary product of vital physiological processes, and have been extracted from the secretions of living beings, and from fresh animal tissues. The following is a list of the principal animal alkaloids so obtained:—

Creatinine, $C_4H_7N_3O$, from urine.

Pseudo-xanthine, $C_4H_5N_3O$, from urine and flesh.

Sarkine, $C_3H_4N_2O$, from urine and flesh.

Xanthine, $C_8H_8N_4O_2$, from urine and flesh.

Crusocreatinine, $C_8H_8N_4O$, from fresh meat.

Xanthocreatinine, $C_8H_{10}N_4O$, from fresh meat.

Guanine, $C_5H_7N_5O$, from flesh and guano.

Carnine, $C_7H_8N_4O_3$, from fresh meat.

Betaine, $C_3H_7NO_2$, from urine.

Mytilotoxine, $C_6H_{15}NO_2$, from poisonous mussels.

Ptomaines and Disease.—Animal alkaloids are being incessantly produced within our bodies as a result of the normal physiological processes, and they are eliminated by the bowels, kidneys, liver, skin, and lungs; but if from any cause these eliminating organs fail to perfectly fulfil their excretory functions, then an accumulation of these alkaloids in the system occurs, and a toxic action is exerted by them on the nervous centres. In this way can be explained the headache resulting from constipation, and the more serious nervous symptoms resulting from deficient excretory action of the kidneys in certain diseases of those organs. The removal of these animal alkaloids is, however, not only effected by the excretory organs, but, in addition, a powerful agent for their destruction is at work in the oxygen of the blood, which is continually oxidising and burning them up; and it seems probable that this combustion to a large extent occurs in the liver. If, the excretory organs remaining sound, there is excessive production of animal alkaloids, but inadequate elimination and destruction—a condition which is obtained in all forms of over-exertion, as in a prolonged march—then accumulation of material elaborated in excess and imperfectly eliminated or destroyed occurs, and an auto-infection, a temporary poisoning of the system, results, the poison affecting the nervous centres, and producing the fever of over-exertion, the fever of prostration.

As regards the infectious fevers, it is probable that after the admission of the specific micro-organisms into the body, and provided they find the conditions suitable, they live and multiply, and that, as a result or a residuum of their vital activity, a powerful alkaloidal or other poison is produced, the toxicity of which is the cause of the symptoms of the disease. If so, each infectious fever is the result of a fermentative decomposition of albuminous matter within the body, induced by a special micro-organism, manufacturing its own peculiar poison for each disease. See ANTITOXINS; BACTERIA; IMMUNITY; and TOXINS.

The chief medico-legal interest attaching to the ptomaines arises from their liability to be confounded with some of the vegetable alkaloids, and hence to the possibility of their leading to mistakes in medico-legal practice. There are no chemical reactions by which the ptomaines as a class may be distinguished from the vegetable alkaloids.

For a description of ptomaines in connection with food-poisoning, see FOOD, POISONOUS.

ARTHUR P. LUFF.

PTOSIS (πτῶσις, a fall).—A drooping or falling of the upper eyelid, with inability to raise it, due to paralysis of the third cranial nerve. See THIRD NERVE, Diseases of.

PTYALISM (πτύαλον, saliva).—A synonym for salivation, or excessive flow of saliva. See SALIVARY SECRETION, Disorders of.

PUBLIC HEALTH.¹—Broadly stated, the aim of Public Health, or Preventive Medicine, is to curtail, and, if possible, prevent diseases, to prolong existence, and to render life happier by means of improved physical conditions. Such care as communities took for the protection of their health was in early times taken under the auspices of religion or morality; it was hardly until the century which has just ended that serious attempts were made to understand the conditions making for health and disease among communities. Although many old statutes and provisions of the common law may be shown to have their bearing upon public health, organised legislation in England for the promotion of this object may be said to date from the Public Health Act, 1848. The country had by this time, under the system of registration inaugurated in 1837, and by the aid of Royal Commissions, learned something as to the causes of death in the population. It was apparent that year after year far more lives were being forfeited to home-grown epidemics than had been lost during the foreign epidemic of 1831–32. By 1848, the threat of fresh invasion by Asiatic cholera had become near and loud. The time for sanitary action was auspicious. It had come to be seen that communities, as such, had duties towards their members and towards other communities, in respect of matters affecting health; and with this enlarged sense of public responsibility it was felt that adequate organisations should be provided, in order to instruct, direct, and even coerce ignorant or wilful members of each community. Needless to say, this function of legislation speedily asserted itself more definitely and in fresh directions; until the present system of sanitary observation and administration has grown up.

Considering, first, the area of a country in its broader aspects, and always with more particular reference to England and the public-health arrangements of England, we note the influences exerted by the *condition of open lands, forests, and rivers*. The drainage of land, so as to carry off water readily, and thus to make both ground and air drier, has a great effect on certain aspects of the public health. Ague, once so common in England, has in consequence of the direct or indirect effects of drainage almost disappeared, as also has dysentery, which so often accompanies it.

The movements of the ground-water, which, by its rises and falls, influence the moisture and the amount of air in the soil, and, through these conditions, alter the amount and rapidity of decomposition therein, have been supposed also to influence health, and to be especially connected with the development of typhoid fever, cholera, and, more recently, diphtheria. One view is that a rising subsoil water may force out from the soil pathogenic organisms, and clearly such organisms may be thus washed into shallow wells. A moist ground is also believed, on tolerably strong evidence, to be favourable to the production of destructive lung-diseases; and rheumatism and catarrhal affections would appear to be more common on damp soils. But more accurate observations are necessary on these points. Although the influence

¹ This article treats in the main of the general principles concerned in the prevention and control of infectious diseases. The scheme devised by Dr. Parkes in the original issue is still adhered to, although parts of the article have been rewritten. Sanitary Law, Vital Statistics, and Bacteriology are dealt with in separate articles.—H. T. B.

of the ground-water in cholera is questionable, and it is by no means always active in the production of typhoid fever, it is certain that lowering the level of the ground-water when it is near the surface is often followed by the best results on the general health of the people, and in hot countries malarial diseases have been greatly diminished, even when the lowering of the ground-water has not exceeded a few inches. But in so far as malaria is concerned, recent researches with regard to the part played by certain species of mosquitoes (p. 949) render it extremely probable that drainage has acted by drying up the pools which are now known to form the breeding-places of the mosquitoes in question. A noteworthy relation has also been observed between the autumnal diarrhoea of children in towns and the earth-temperature at a depth of four feet, and recent researches confirm this observation.

The regulation of irrigation operations also has in some countries become an important question.

The control of forests ought to be considered a State matter, as the climate of a country and, therefore, health may be greatly influenced by them. In England such regulation of forests is not a matter of much national importance; it is otherwise in Germany and France, where laws exist which restrain private action; and in Italy, Greece, and Turkey the condition of the forests requires grave consideration as a matter of public health, as well as of climate and rainfall. In India this is also the case, and there are several important sanitary aspects under which the operations of the Forest Department need to be regarded.

The regulation of rivers, such as the embankments, narrowings, deepenings, and removal of obstructions, has generally been concerned with little else than navigation or the prevention of accumulations; but rivers are equally important from a sanitary standpoint, as they may influence the out-flow of the land-water from their drainage areas, and in that way may affect the level of the subsoil water and the dryness of the soil.

In another way the regulation of rivers is a matter of the greatest importance. They supply the drinking-water of the community to a large extent, and freedom from contamination is, therefore, necessary. For years this has been seen to form one of the most difficult questions of public health, and for some years a Royal Commission was engaged in inquiring into the causes and remedies of the pollution of rivers. A Second Commission presented its Report in special relation to supplies of drinking-water for London, and the decision of a Royal Commission which is at the present time considering the best means of sewage purification, and which has now issued an interim report recommending further administrative machinery, is likely to have an important effect upon the purity of our rivers. The chief causes of contamination are the dirty water and sewage coming from towns, and the refuse of trade operations. The former can in some measure be met by irrigation or by filtration through land, though the immense quantity of water to be purified and the price or position of land may cause difficulty. The admixture of trade refuse-water presents, however, the greater difficulty; yet to prohibit the flow into streams would sometimes be to prohibit the trade works. At present there is no settled general standard of purity for either town or trade water before its discharge into streams. Such standards were suggested by the

Rivers Pollution Prevention Commissioners, but they have never been accepted either by Parliament or the public, and it will perhaps be eventually recognised that for actual working the standard must vary with the place and trade, and must depend first on the demands made upon the river for drinking use; and, for the rest, on the purity of the river water into which the dirty effluent is discharged, and the comparative volumes of dirty and clean water thus mixed together—i.e. upon the extent of the dilution of the impure with the pure water. The number and kind of fish living in the river water are also to be taken into account, effluents of the highest obtainable purity only being admitted into trout or salmon rivers, or into those estuaries in which shell-fish such as oysters are cultivated for market. Thus it will be seen that, at present, no great progress has been made in the prevention of the pollution of rivers in England, the interests involved in the continuance of the polluted condition of streams being exceedingly strong, and the enforcement of the law being in the hands of authorities who are often the greatest offenders against its provisions. County Councils, however, who are now possessed of considerable sanitary functions, have been empowered to enforce the provisions of the Rivers Pollution Acts, and on the initiation of these Councils Joint Committees may be and have been formed to control the pollution of a river through its whole course. Much good has already resulted from the action of these bodies, who are to a certain extent free from the trammels of petty and local interests.

Of conditions operative upon the health of the individual and of the community, the one that falls most conspicuously within the province of *Local Sanitary Authorities*, as of the Legislature which created them, is the condition under which people have their dwelling—the state and circumstances of their *habitation*, both in the particular and in the aggregate. So true is this, and so strongly is this consideration felt in practice, that, for the rest, it will be convenient to arrange the subject-matters of the present article with the notion of condition of habitation in the foreground; and to regard each subject as it principally concerns communities inhabiting a larger or smaller place, or as it concerns the particular habitation. Thus, the general subject of public health will, with little exception, be here discussed with reference, first, to collections of houses forming cities, towns, and villages; secondly, to separate houses.

Cities, Towns and Villages.—The health of the inhabitants of English towns, as judged of by the annual rate of mortality, is not so good as that of the people of rural districts. See MORTALITY; and VITAL STATISTICS.

Hygienic Conditions of Cities, Towns, and Villages.—These are conditions referable to:

1. The site and soil.
2. The arrangement and building of houses.
3. The water-supply.
4. The removal of refuse-water and of dry refuse.
5. The removal of excreta.
6. The conservancy of the surface.
7. The supply of food, including the regulation of slaughter-houses, dairies, and bake-houses.
8. The regulation of trades.
9. The arrest and control of infectious diseases.
10. The disposal of the dead.
11. The supervision of nuisances.

1. *The Site and Soil.*—The sites of old cities were fixed by reason of war or commerce, or of vicinity to water-supply; when modern cities arise, it is often in consequence of the development of new industries, such as depend on coal and iron, or such as cotton or woollen works, where the site is determined by convenience of manufactures. In England, even at the present day, new towns and villages still tend to spring up without regulation, and when they attain a certain size, and some sort of municipal government is formed, it is often too late to consider the wholesomeness of the ground or to attend to the arrangement and construction of the existing houses. It were to be desired that the Legislature should secure for towns, during their period of growth and extension, more attention to such matters. For too often in the case of old towns Local Improvement or Health Acts are found to be needed, in order to remedy slowly and laboriously the errors of bygone times.

In respect of the *site* it is necessary to dry the ground if it is at all damp, and to keep it from being contaminated by injurious or offensive matters. It is one of the advantages of sewerage towns that the ground is thereby drained; and brick sewers were formerly laid so as to admit subsoil water and drain the ground as well as to serve as channels for house-waters. For the former object of drying the soil, every town ought to have a system of pervious sewers; and for the second object, it is best to have a system of impervious sewers combined with the deep drainage of the soil. There should be no cesspits or middens, or manure-heaps, in uncemented holes; all refuse of this kind should be removed and never allowed to soak into the ground. The ground ought to be secured against every source of contamination, a fact which, with a fuller knowledge of the behaviour of pathogenic organisms in soil, is becoming of more and more importance. Paving of all streets and courts, so as to prevent surface-impurities from soaking in, and great care in the construction of private drains and public sewers, will keep the soil of a city free from those impurities which, under the influence of heat, water, and air, generate injurious effluvia that may be sucked into houses. It is necessary also to have rules as to 'made ground.' Inequalities in the surface of the ground are often levelled by filling in with refuse of all kinds; house and chemical refuse, and dreggings from rivers, with other rubbish, are sometimes used. Decomposition goes on in such soils, and eventually, if not too foul, they purify themselves, but for this time is required. In the 'cinder refuse' of Liverpool, which is tolerably free from impurities, at least three years are required for the disappearance of the more easily decomposed animal and vegetable matters. In other made soils it may be longer; and when soil is very impure, as in the case of old graveyards, it is uncertain how long it is before it would be safe to build upon it. Sanitary authorities have, under certain conditions, power to prevent new buildings from being erected on ground upon which animal or vegetable matter has been deposited. Every made soil should be well drained, so that air and water may freely pass through it, and the best should have been laid down for three or four years before being built upon. Trial holes should be made in all cases of doubt.

The leakage of coal-gas from pipes is a point to

be guarded against, and the ease of preventing this would be much increased by the use of subways, such as are to be found in certain European cities.

With respect to the means of covering the sides of city streets for foot passengers, good stone paving or the like is essential; for it greatly increases the ease of cleaning the surface. Full powers are given to Sanitary Authorities for this purpose.

The question of the best kind of road for horse and carriage traffic is not quite so easily settled; there are four principal plans: macadamising, granite blocks, wood, and asphalt. As a mere matter of health the last is probably preferable; there is less *débris*, greater ease of cleaning, and less noise. Both macadamised and granite-block roads soon get worn into fine mud, which is made up of finely comminuted stone mixed with droppings from horses, and the like. In wet weather this is washed into the sewers, which it aids in obstructing, and it forms a useless part of the sewage. In dry weather it becomes pulverised, floats in the air and is one of the ingredients of city air, from which it is deposited as dust. Wood and asphalt break up much more slowly and are more easily cleaned both by rain and by washing, but it is necessary that the wood used should be as hard and impervious as possible.

2. *The Arrangement and Building of Houses.*—The arrangement of houses and streets in towns is influenced by many circumstances. A good return for money, facility of locomotion, and beauty, are the chief considerations in new towns. In old cities questions of defence and of materials have especially regulated the size and direction of their streets, and the height and compression of their houses. Many considerations will always influence the formation of streets, but a free passage of air to all parts of a town is a cardinal point, which should receive the utmost attention. The more numerous and the wider the streets are, the less impeded will be the air-flow. It is undesirable that a street should be less in width than one and a half times the height of the houses abutting thereon.

There should be open spaces, arranged to allow ready movement of air through them at the back of the houses, and all 'back-to-back' building should be illegal. The erection of narrow lanes and alleys should be prohibited in all new towns, and the back courts so common in our older towns ought to be gradually removed. Additional open spaces should be provided at intervals. Wide straight streets are useful for ventilation, and are best for the laying of pipes and tramways. Straight lines are by some not considered beautiful, but generally speaking they are certainly most convenient.

Powers are given to Urban Authorities to make by-laws regulating the width of new streets, providing for sewerage, foundation of houses, spaces for air about houses, the drainage of buildings, and many other matters. As regards existing towns, these Authorities are enabled to purchase dwellings in order to improve streets, to set back houses when rebuilt, and in cases where only the front of a house in a street is taken down they may prescribe the line of the new building. Larger powers of demolition and reconstruction, moreover, are given by the Housing of the Working Classes Acts, the facilities for the administration of which have been quite recently extended, and various local statutes. It has been said that due provision

should be made beforehand for the proper construction of the many new towns which must needs spring up in the course of another century. The case seems clear for the community at large to regulate matters so important as these for the general health of the population are proper for Imperial legislation to deal with to a greater degree than has been yet recognised in any Act. In their principles at least, such matters should not be relegated to Local Authorities, for them to accept and to use according to the local caprice of the moment.

An important point to determine is the height of the houses, a matter which is assuming serious dimensions in London and other of our large towns. In England a large proportion of our towns consists of low brick houses. If these are not too crowded they give a good distribution of the inhabitants, and oppose little obstacle to the movement of air and the distribution of light. When the houses are very lofty the air-currents must be much more impeded, and therefore the streets ought to be much wider, and open spaces behind and about them ought to be more carefully secured, a point which has been much neglected in the erection of modern blocks of 'flats.' It is not possible to state with any precision the number of persons who may be located on an acre—this will depend in the main on the construction of the individual houses; but it may be laid down as a general rule that, however small be the size of the houses, the amount of ground not occupied by them in any given acre should be as great as the amount actually taken up by houses, and such a rule should *à fortiori* be maintained in the case of more populous houses. Where the houses of a town are intended, each of them, for the lodgment of several families, and consist (with the name of 'flats' or 'mansions') of a number of separate dwellings piled up on the top of each other, it is of even greater importance that the relation between inhabited and uninhabited area should be properly regulated. Such flats or mansions ought, for the sake of air and light, to be provided with exceptional arrangements for space about them, with, concurrently, abundant ventilation of streets and provision of open spaces. They may serve to illustrate the foregoing contention as to the need for supervision by an Imperial or at least a county authority over the arrangements of streets and houses; for every Local Authority can hardly be expected to be sufficiently alive to the misfortunes that have befallen certain large towns through want of due regulation of houses of this class. The construction of the separate houses should not be altogether a matter of absolute control by a municipality; and certain rules as to ground-plan, foundations, arrangement of closets, and the thickness of party walls are habitually enjoined by the State upon Local Authorities desirous of regulating their new buildings; while sufficient liberty should be afforded to the requirements and tastes of individual owners and architects.

So in all houses, whether urban or rural, there should be means of ventilation for every room; no inhabited room should have a borrowed light, but should have a window opening directly on the external air; every window should open, and especially at the top; every room should be of good height, not less than nine feet in the smallest, and ten and eleven feet in larger rooms; the closets should, when practicable, be arranged in such a

manner that, in addition to ventilation of the closet itself, there should be thorough cross ventilation into the open air between the closet and the rest of the house, and this is best accomplished by having projecting portions of the building to contain the closets; every house should be provided with closets in due proportion to its population; there should be proper water-supply, with easily inspected storage, if house-storage is permitted, and easy and efficient methods of carrying off the dirty house-water: there should be proper arrangements for the collection and temporary storage of dry house refuse; and house drains and pipes should be constructed and ventilated on the principles that will presently be set forth.

All these matters are easy to regulate without interfering unduly with the plans of the architect.

3. *The Water-supply.*—In a town with sewers and water-closets it is generally considered that the supply of water per head daily should not be less than 25 gallons; and if there are trades using large quantities of water, from five to ten gallons additional (reckoned per head of population) are wanted for the town. If there are no water-closets, from 14 to 20 gallons per head daily appears to be the amount usually considered sufficient in large English towns.

The sources of supply are natural lakes, artificial lakes and gathering grounds, rivers, springs, and wells. In towns of any size superficial and shallow wells are always suspicious sources. Local authorities have powers to undertake the public supply of water, and to protect water-supplies; also to close wells, tanks, cisterns, or pumps if the water be polluted. But additional general powers are urgently required to enable a well to be closed in the event of its surroundings being such as to threaten the purity of the water.

The following are the matters of chief importance in towns: (a) The supply should be taken from sources capable of affording a quantity adequate to the present and proximate wants of the town, with such approach to constancy as may be attainable. In quality, the great points are to ensure that the water is clear or is easily or completely freed from sediment by sand-filtration, and is well aerated, pleasant to taste, and without smell; that it contains no injurious animal constituents, and cannot become contaminated with excreta of men or animals, or with foul water from houses; that it contains no injurious amount of vegetable matter (not more than 2 or 3 grains per gallon), and that its mineral constituents are of moderate amount, and consisting of such mineral matters as are not likely to be injurious. With respect to lime especially, much discussion has taken place as to whether soft or temporarily hard (from calcium carbonate) water is best for a town; the soft water is preferred for many trades and is probably best for health, though it has been found impossible to prove this by statistics; it is certain that the inhabitants of numerous towns using a good chalk water have excellent health, and it would seem in fact that the question between water hard from calcium carbonate and soft water is not an important one. The use, however, of hard water leads to enormous waste of soap, is liable to block up cisterns and pipes by a deposit of 'fur,' and is said to be bad for cooking purposes. When water is *permanently* hard from calcium chloride and sulphate it is thought to be objectionable

to health. The great point in choosing water is, in practice, its freedom from any chance of contamination with excreta, or with refuse matter from habitations.

The duties of a medical officer of health should include the supervision of the sources of supply, so as to detect and prevent any possible contamination, and such officer should have legal access at all times to the premises of any Water Company supplying his district with water. Frequent bacteriological, as well as chemical, examinations of the water should be made.

The water when supplied, except in the case of deep-well waters, most commonly needs to be stored and filtered. The reservoirs of our towns contain from one to three months' supply, or less if the supply is very uniform in quantity. The reservoirs require to be placed so as to be clear of trees, and protected from danger of anything being thrown into them. Filters which aim at straining off matter in suspension and oxidising organic substances are usually made of sand about 3 feet in depth resting upon gravel, and the filtration, according to Koch, should be so conducted that (a) the pace should not exceed 3·94 inches per hour, each filter being provided with a regulating contrivance; (b) the water from each filter should be examined bacteriologically once daily; (c) the filtered water should contain no more than 100 micro-organisms per cubic centimetre. Where there is no public supply and domestic filters are used, frequent cleaning is essential. Filters made of unglazed porcelain or of infusorial earth are the most reliable.

After filtration the water is distributed by means of mains usually of iron tarred or varnished inside, for the larger conduits, and then by leaden service-pipes, or, under certain circumstances, tinned-lead pipes, for the smaller. Both iron and lead, and especially the latter, are dissolved by some waters, and the question whether lead is so dissolved has often to be answered; in examining into this matter the water should be taken after it has been in contact with the pipes for some hours—for instance, in the early morning.

Carried down the public pipes, the water is either delivered at intervals to house-cisterns, or, what is far better, is supplied on the constant plan without house-storage. If it be not possible to dispense with house-cisterns, they should be well made of slate, stoneware, or galvanised iron, should be able to be easily inspected and cleaned, and their overflow pipes should always end in the open air, never go into any drain. The greatest care should be taken that the cistern-water shall run no risk of contamination by absorption of foul air or by soakage into the cistern, which should be well covered to prevent dust getting in.

If the 'constant system' is in force, it should be truly constant, for if the water is cut off at intervals and the house-pipes are then emptied, or if leakages take place in the street mains, air must be drawn into them, and this air may be foul; it has even happened that dirty liquids have been sucked into water-pipes, as where a closet service-pipe direct from the house-main has been connected with a choked closet-pan, and in this way excreta have not only passed into these house-pipes, but have even got into the mains. In a similar manner, when sewers are laid in the same trenches as water-mains, liquids escaping from leaky sewers may find their way through bad joints or fissures in water-

pipes. That is most liable to occur during intermissions in the water-service; but the same insuction into water-pipes may occur while the pipes are full, if the water be running through them with great velocity. This fact is not sufficiently recognised, even by water-engineers; yet it has been concerned in the distribution of enteric fever broadcast in a community.

Under a constant system and under an intermittent system alike, small service-cisterns are needed for water-closets and for kitchen-boilers, and precautions have to be taken with these cisterns equally with larger storage-cisterns. In fact, too great care cannot be taken in thoroughly guarding water-pipes and cisterns in every way. Waste-pipes from cisterns must have no connection with the drains, but should discharge freely in the open air.

The sources of contamination of drinking-water are very numerous, and may affect the water at its source, in its flow, in the reservoir, or during distribution. If stored in houses it is especially exposed to risk; and this is the grand argument for constant service, that the water may be delivered immediately after filtration. The plan of cistern-storage, indeed, lessens those risks that are incidental to intermissions; but this plan demands that cisterns be properly made and placed, and be regularly cleaned. For low-rented houses these conditions are very difficult of attainment, and therefore the constant service is peculiarly adapted to the houses of the poor.

In all towns the service should be at high pressure, so that water may be carried to every floor and thus labour be spared, and the freshness of the water be secured. In places where the water is not carried into the houses, but is fetched from pumps or from 'hydrants' in the street, it has to be stored in the houses in buckets, and runs many chances of impurity.

A town requires water for public purposes, such as for public baths, washhouses, flooding and washing streets, flushing sewers, and putting out fires, and for this latter purpose sufficient and constant pressure is essential. Statutory powers are given for carrying out these objects.

4. *The Disposal of Dirty House-water and Dry Refuse.*—After being distributed and used in houses or trades, the water with the impurities it has gathered must be carried out of the town. The inhabitants should have no difficulty in getting rid of their dirty water, or otherwise dirty water will come to be used improperly several times over. Houses ought to have convenient sinks discharging by trapped pipes opening outside the house, not into a drain, but over a grating in connection with a trapped inlet or gully, in the manner provided for in the Model By-laws. From these it must go along pipes or sewers, and be disposed of at the outfall in some way. House-water, besides other impurities, frequently includes some portion of urine which, as we now know, may contain certain pathogenic organisms. It is not fit to be at once discharged into streams, but as its fertilising powers are considerable it is well adapted for irrigation on land. The plan involving the least expense appears to be to filter it by intermittent filtration on a small but sufficient area of properly prepared and drained ground, provided such can be procured.

The dry refuse of houses consists of cinders and ashes, remains of food, dust from sweepings, and

various other used-up articles of house life. In some towns there is little difficulty in disposing of this refuse. After being carted away it is sorted, and every article finds a sale. In other towns, however, the disposal of the house-refuse is a matter of difficulty and expense. A system of destroying the refuse by fire in destructor furnaces has of late years come largely into use in various towns and is making rapid progress. The refuse contains a sufficiency of combustible material in the shape of cinders to ensure its complete destruction in a properly designed furnace, and the waste heat may be utilised for various municipal purposes, e.g. for converting the contents of pail-closets into a dry manure, or for generating steam in boilers for driving electric-lighting machinery. The clinkers, when withdrawn from the furnace, can be ground down in a mortar-mill and converted into mortar, bricks, or concrete. Sanitarily considered, the destruction by heat of dust-bin refuse is far preferable to the old-fashioned sorting method. In some places the dry refuse is placed every day by the inhabitants in front of the houses and is removed by scavengers. In other places there must be storage of refuse on the premises for a varying number of days; if this is requisite, every house should have a properly prepared dust-bin, well paved to prevent soakage, well covered so that its contents may be kept dry and free from the influences of wind, and so placed as to be away from the house, though convenient for the house as well as for the town-savengers. In the building of any house the arrangements for the position of the dust-bin are almost as important as those for the closets. Of late, galvanised iron pails with tight-fitting lids have come largely into use to replace brick dust-bins for the storage of dry house-refuse, and being non-absorbent they are far more cleanly and suitable receptacles than brick structures could ever be. The removal ought to be frequent and regular, but the frequency has to be fixed by special circumstances. As far as possible organic refuse (food scraps &c.) should be burnt in the kitchen fire, and not stored on the premises to await removal by the scavengers.

5. *The Removal of Excreta.*—The excreta of the skin and lungs are got rid of by ventilation and washing, so that this heading refers only to the solid and liquid excrements. These average respectively (for both sexes and all ages) about $2\frac{1}{2}$ ounces avoirdupois of solid excrement and 40 fluid ounces of urine per diem.

The excreta must not soak into the earth, or remain near dwellings. The common privy and the 'midden' of northern towns can only with difficulty be brought to fulfil these conditions. In towns above 10,000 inhabitants it now seems clear that there is no possibility of using the earth-closet system, on account of the expense of preparation and transport of dry earth. Therefore, for towns in this country, two plans alone remain: (1) The dry plan with frequent removal, with perhaps such deodorisation as the ashes of the house may give; the so-called 'pail system' is one form of this dry plan. (2) The 'water system,' the excreta being carried off from the house along drains and sewers, by the aid of water. The air or pneumatic systems of Liernur and Berlier, which are in use in certain parts of the Continent, and by which the excreta, unmixed with water, are sucked through pipes into

a central reservoir by an air-pump, worked by a steam-engine, are perhaps not altogether well suited to English ideas and habits.

It would not be possible to discuss here the relative value and the technical details of the pail- and the water-systems. Both are largely used in England. The pail-system, as the most adaptable (among dry systems) to the conditions of a town, has been used in towns where proper sewers cannot be made or water is deficient, or where land cannot be obtained for irrigation or filtration, owing to the expenses involved. It has the disadvantage of being opposed to one of the first principles of sanitation in that it keeps the excreta for some days near the house, besides being sometimes attended with nuisances in the working. But, nevertheless, it is capable of keeping a town fairly clean when it is properly carried out, and it is an immense advance over the old 'midden' and 'cesspool' systems, which retained the excreta in the filthiest receptacles for long periods in the very midst of the people. It is of the essence of the pail-system that the removal of the excreta should be frequent, that is, if practicable, every day. After removal, the excreta are applied at once to the land, or are made into 'poudrette.' In some towns the house-ashes are thrown on a wire screen, so as to allow the fine ash to fall on the excreta—this is sometimes called the 'ash plan'; in other cases deodorants are used. The 'Goux system' is to place some absorbent material round the interior of the pail to absorb the urine.

The water-system is more elaborate, and probably more expensive, but if properly carried out is more effectual. If a town can make good sewers, and can find water for flushing and proper means for disposal of the sewage, the water-system would certainly appear to be the best for health and general comfort.

There cannot be many towns which could not acquire the quantity of water needed for the proper use of a water-system. By some simple contrivances waste water—the water that has been put to other domestic purposes—can be made use of for washing out the closets. Slop-closets and trough-closets, in which these contrivances are used, are found to work efficiently, and to economise water in places where there is but scant supply.

The drainage of every house that discharges its excrements by the water-system should possess the following arrangements for disconnecting the drain-air from the air of the common sewer, and for dispersing the foul air of its own particular drain: (a) near the junction with the sewer the house-drain should be provided with a 'siphon-trap,' through which all the liquids of the house must pass, and which, therefore, must always be charged with water while the house is inhabited; (b) an opening from the outside air to the house-drain, made on the outside of the siphon-trap, to serve as an inlet to the house-drainage ventilating system; the outlet of this system being (c) a pipe in continuation of the farther end of the drain carried up 'full-bore' above the roof, its end at this spot being left open, save for a wire-grating to prevent leaves or other wind-borne substances from being deposited therein. Means of inspection and of access to the house-drains should be provided at convenient situations.

It is essential that sewers should be well constructed; they should allow no deposit; and they should be thoroughly ventilated. Deposits are prevented by having egg-shaped sewers with a proper

fall, easy means of access for inspection and cleaning, and a regular flow of water, with periodical flushing. The ventilation of sewers is perhaps best effected by having numerous openings—as many, in fact, as can be made—so as to allow constant and free interchange between the sewer-air and the atmosphere. These openings may be by street-gratings or by special shafts of sufficient calibre, according to circumstances. Ventilation through furnace-chimneys is inadvisable, and is of no avail for distant portions of the sewers. For the dead ends of sewers and in narrow streets and courts, shafts of not less than 6 inches diameter, carried up from the crown of the sewer to above the roofs of the houses, should be provided. But in whatever way the ventilation is carried out, the rule must be to have the freest communication between the sewer-air and the general atmosphere. This free ventilation occasions no offence if the sewers are properly made and kept; while, if the air of sewers at the ventilators is found offensive, the ventilation will at least have provided against the more dangerous discharge of the foul air into houses.

Sewers have been objected to on account of the alleged occasional spread of typhoid fever and diarrhoeal affections, and perhaps of cholera and diphtheria, by their agency; but, if properly arranged, and with disconnection between the sewer and houses, there should be no danger, and recent work with regard to the bacteria in sewage and in the air of sewers tends to support this view. It is difficult to see how sewers can be displaced, or any other plan be substituted for them, in a town. The house-water must be carried off, and it is impure even if no excreta are allowed to flow in. Even if the pail- or other system for disposal of excrement be adopted, there must still be town sewers for dirty house-water, and all the precautions above alluded to must be enforced. Sewers, then, whether or not they receive the excreta of a town, are a necessity, and with proper construction and management they should be solely beneficial to the public health. It is to a certain extent a question of engineering detail whether the sewers carrying the house-water should also carry off the rain-water; but there would seem to be considerable sanitary advantages in the 'separate' system by which different channels are provided for house-sewage and rain-water: the chief, perhaps, being that under this system impermeable pipe-sewers of small diameter may be used to convey the sewage, and that the amount being more constant than when a rainfall is admitted, there is less difficulty in dealing with the sewage for purification purposes. Moreover, the sewage is richer in fertilising properties. Wherever towns situated on moist grounds have adopted a system of impermeable sewers for conveying away waste-waters and excreta from houses, means should be taken to dry the subsoil by laying porous drains at a sufficient depth. The rain and surface-waters may be carried off by surface-channels and gutters, where the levels permit, or in other cases by the subsoil drains.

The subject of purification and disposal of sewage which, as has been stated, is now under consideration of a Royal Commission, has received much attention of late owing to the progress of our knowledge as to the action of bacteria in the liquefaction and 'nitrification' of sewage. Briefly stated, sewage may be purified in a larger or smaller degree by mechanical, chemical, and biological agencies, and in practice a combination of such agencies is fre-

quently made use of. Each has its advantage at certain periods and under certain circumstances, and the manner of application of the several agencies is by *Screening*, *Chemical Precipitation*, with *Sedimentation*, *Filtration* (including under this term *Irrigation*), and *Liquefaction* in what is known as the 'Septic Tank.' A few words only can be said in reference to each.

Screening and Deposit are almost essential preliminaries to many methods of treatment in order to separate out from the sewage solid organic and inorganic bodies. Grit-chambers fixed on revolving screens are usually used. What are known as 'Roughing Filters' are sometimes employed.

Chemical Precipitation by aid of chemicals, such as lime, alumina, iron salts, and many other substances, either alone or in combination, seeks, by forming a precipitate, to arrest and carry down, during the process of sedimentation in settling tanks, much of the suspended matter—including, doubtless, a number of the bacteria originally present—together with an uncertain amount of the organic substance in solution. Although the effluent is often clear in appearance, it contains the chlorides and ammonia, and further treatment by filtration or irrigation is necessary to oxidise the organic matter remaining. One of the great drawbacks to precipitation-processes is the difficulty of disposing of the resulting sludge.

Filtration is used either alone or in conjunction with chemical precipitation or the septic tank process. Filters of many substances have been, and are being used, and the object of all, be they of earth, coke, ballast, &c., is, besides separating suspended substances, to oxidise the organic matter. It is necessary to provide, by periods of rest or in other ways, that the filtering material may be duly aerated. In some cases the filter is quite filled with sewage, and allowed to remain thus for a considerable period, the filter being then known as a 'contact' filter; in others the filtration is for the time being continuous. In each case periods of rest for aeration are necessary, and the several filters in use at the present time differ from one another, not only as to the nature and size of the material used, but also in the manner in which aeration is brought about. The principle involved in each case is how best to utilise the bacteria already present, which on the one hand act in the absence of air, and on the other require air for their operations, but it is probable that both aerobic and anaerobic bacteria are partially operative in all instances. When land is used as a filtering agent, it is necessary in most instances to under-drain it, the object of land-filtration being 'the concentration of sewage at short intervals on an area of specially chosen porous ground as small as will absorb and cleanse it, not excluding vegetation, but making the produce of secondary importance.' When, however, the land is used for what is known as *Broad Irrigation*, and where under-draining is not absolutely essential, the object is 'the distribution of sewage over a large surface of ordinary agricultural land, having in view a maximum growth of vegetation (consistent with due purification) for the amount of sewage supplied.'

The 'Septic Tank' or *Liquefaction* process, which was first introduced at Exeter, where it is still in use, consists in allowing the crude sewage to pass slowly (in about 24 hours) through a closed tank from which light and air are excluded. It is

found that during the passage the solids have become liquefied, mainly, it is believed, through the action of the anaërobic organisms; the sewage on leaving the tank being passed through coke-breeze or other filters. The action of the tank may be regarded as roughly similar in principle to that which takes place in the coarse filters of other biological processes.

6. *The Conservancy of the Surface Area.*—The cleansing of the surface-area of towns has long been a function of the public Authority. The sanitary importance of thorough surface-cleansing is obvious; the mud and dirt of towns and refuse of all kinds, wetted by rain and exposed to heat, soon decompose and give out injurious effluvia, especially in narrow courts and lanes where the movement of air is impeded. The necessity of such cleansing is becoming more and more apparent as our knowledge of the relation between polluted soil and disease increases. Public streets of all kinds can be easily kept clean, but want of paving and consequent foulness on private premises require to be sought out. Especially this is of importance where (as in the case of pigsties and stables) neglect of surface-cleansing may give rise to nuisances injurious to health.

7. *The Supply of Food, including the Regulation of Slaughter-houses, Dairies, and Bake-houses.*—A very important duty of a municipality, and one to which more attention is being daily paid, is to supervise the food of the people. While the price and quality must be left to the ordinary operations of commerce, the responsibility of preventing falsifications, and of ensuring that the article shall not be injurious to health, is devolved upon County Councils and on Sanitary Authorities. It is to these latter bodies that the regulation of slaughter-houses and knackers' yards is entrusted. Private *slaughter-houses* may be licensed, and can be visited and subjected to by-laws. They are often constructed out of buildings intended for other purposes, are not fitted with proper appliances, and are generally placed in the densest part of the town. The evils attending them are gradually being removed by the erection of public slaughter-houses, where abundant air, water, good sewers, and means of cleansing obtain, and where facilities for the skilled inspection of beasts and meat, and for the refrigeration of the latter, are, or should be, available. The custom of slaughtering in the country and then sending the meat to cities is increasing, and this again renders private slaughter-houses less necessary.

The transport of cattle and sheep to towns is a matter of very great importance as respects both the goodness of the meat and the comfort of the animals. Space in the trucks, supply of water and food, length of journeys, and other matters, require regulation.

Cow-houses, Dairies, and Milk-shops are now inspected by Sanitary Authorities, in pursuance of the powers of the Dairies, Cow-sheds, and Milk-shops Order of 1885 and of later amending Orders. These orders contain provisions for the registration of cow-keepers, dairymen, and purveyors of milk; for regulating the lighting, ventilation, cleansing, drainage, and water-supply of dairies, cow-sheds, and milk-shops; and prescribe the precautions that must be taken to guard milk against exposure to

infection or contamination. These latter precautions are especially necessary in the light of the knowledge we now possess of the spread of epidemics of enteric fever, scarlet fever, and diphtheria among human communities by the agency of milk; and it is gradually becoming more and more certain that if these disease outbreaks are to be effectually limited, not only must the sanitary arrangements of dairies and cow-sheds be under better and constant supervision, so that the milk may receive no impurities from water, air, or attendants, but that the animals themselves must be periodically inspected; for there is now evidence to hand that diseased conditions of the cows themselves may be the means of imbuing the milk with infective properties. It will be sufficient to mention two diseases alone, namely, tuberculosis and scarlet fever. The experiments recently conducted with tuberculous milk leave little room for doubt that such milk may be instrumental in conveying tuberculosis to human beings, and this notwithstanding the experiments and expression of opinion by Professor Koch to the effect that human tuberculosis is not communicable by bovines. In respect of the latter disease there is evidence pointing to the conclusion that the disease known as the 'Hendon' cow-disease is closely similar in character to human scarlet fever. The growing practice, more particularly on the Continent, of pasteurising milk and cream will do much to reduce the risks of conveying specific disease through the agency of milk, cream, and butter, while the wider application of the tuberculin-test to milch cattle will result in much good in regard to tuberculosis alone. Milk from cows with tuberculous udders may not now be used for human consumption.

Bake-houses are required by law to be kept in a cleanly condition, to be properly ventilated and protected from effluvia, and not to be used as a sleeping-place.

The inspection of the chief *articles of food*, in respect of their wholesomeness, is entrusted to Sanitary Authorities, and has reference to meat, game, poultry, fish, fruit, vegetables, corn, bread, flour, and milk.

The following are the chief sanitary points in each case:—

Meat.—Much doubt exists as to the extent to which the condemnation of meat exposed to sale should be carried. There is no doubt that meat sufficiently decomposed to be discoloured and to have a putrid smell, and meat with abscesses and suppurations, should be condemned, but the difficulty arises with meat apparently sound or not very obviously otherwise, but which is derived from diseased animals.

It is impracticable with our present limited knowledge to determine in all cases by inspection of the dead meat whether disease has been present during life, and the proper safeguard is to be found in an examination by skilled inspectors of the living animal and of the carcase after death, a combination which can only be adequately carried out in public slaughter-houses. Precautions of this nature are the more necessary since, in several instances, meat responsible for outbreaks of poisoning has presented a not unhealthy appearance. It is, too, essential that meat, some of which is thought to have produced illness should be examined as early as possible, rather than after putrefactive organisms have

replaced the pathogenic bacteria. For instance, Durham has recently shown that the *Bacillus enteritidis* of Gärtner, which has been regarded as responsible for numerous outbreaks of poisoning, may be found much more readily if the examination be made early. Meat may produce injurious effects by means of poisonous drugs or foods taken by the animal, by *leucomaines* and *toxins* produced in the living body, from pathogenic bacteria or their products, and by *post-mortem* changes. One or another form of pig's flesh has been responsible for numerous outbreaks of food-poisoning, and what is known as *Botulism* or sausage-poisoning has been common in Germany, where much raw meat is consumed. Cooking may be thought of as likely to destroy certain pathogenic organisms, but those situated in the centre of a roll of meat are likely to escape. Moreover, heat employed may not suffice to render harmless all bacterial products. It seems, however, that the toxin of the *B. botulinus* is rendered inactive by a heat of from 60°–70° C. A specific microbe was found by Klein to be associated with an outbreak of infectious pneumonia at Middlesborough, and the same observer discovered in ham, which was supposed to have given rise to 'Welbeck Disease,' certain bacilli, cultures of which produced the same symptoms when given to guinea-pigs and white mice.

Though opinions differ on this point, and there is obviously need of far more exact knowledge upon the subject, it may perhaps be said that meat derived from animals slaughtered in the early stages of inflammatory diseases and of epidemic pleuro-pneumonia may be used, but that beef from cattle dead of cattle-plague and anthrax (malignant pustule), mutton from sheep with small-pox and splenic apoplexy, and pork from pigs with carbuncular diseases, hog-cholera, hog-typhus, and scarlet fever, should not be used, although it is not easy to give conclusive evidence against all these diseases, as injuring the health of consumers of the meat. Cattle-plague meat, for example, has been largely used without apparent injury. Opinions are much divided as to whether the flesh of braxy sheep, or of cattle dead of foot-and-mouth disease, should be used or not, but it is certainly best to act on the safe side, and the affected parts should not be used. Meat obtained from animals which were suffering from pyæmia, septicæmia or puerperal fever has apparently been responsible for certain outbreaks, and calves and young pigs seem to be prone to septicæmic disorders.

In the case of the parasitic diseases of animals the question is easier. It is of course highly dangerous to use pork infected with *Trichina*. *Cysticerci* in pork, beef, and mutton should also be a valid ground for not permitting the sale, for it is not enough to expect the destruction of the parasite by the cooking that the meat will receive. If it be contended that the prohibition would affect supply, the answer is to be found in the consideration that breeders and salesmen would take greater care in preserving the cattle from parasitic infection; and that this can be done, by supplying pure water and clean food, is shown by the experience of Upper India.

Flukes in the liver do not constitute a valid ground of rejection of the meat, though the liver ought not to be eaten.

On the whole, it may be said that it is certainly wiser to condemn all meat which is derived from

diseased animals, even when the animals are slaughtered, and most certainly when they have died of disease, for there are possible risks in the consumption of such food, and the State is warranted in interfering to prevent the individual being exposed to any such dangers.

The subject of tuberculous meat has within recent years been considered by two Royal Commissions. The evidence adduced, both experimental and other, was held to justify the inference that human tuberculosis can be acquired by the consumption of tuberculous meat; but, having regard to the general custom of cooking meat, and provided due care be taken to exclude obviously tuberculous material, it would seem that actual danger may in the past have been somewhat exaggerated.

The last Royal Commission advised the observation of the following principles in the inspection of tuberculous carcasses of cattle:—

- | | |
|--|---|
| (a) When there is milary tuberculosis of both lungs | The entire carcass, and all the organs, may be seized. |
| (b) When tuberculous lesions are present on the pleura and peritoneum | |
| (c) When tuberculous lesions are present in the muscular system, or in the lymphatic glands embedded in or between the muscles | |
| (d) When tuberculous lesions exist in any part of an emaciated carcass | |
| (a) When the lesions are confined to the lungs and the thoracic lymphatic glands | The carcass, if otherwise healthy, shall not be condemned; but every part of it containing tuberculous lesions shall be seized. |
| (b) When the lesions are confined to the liver | |
| (c) When the lesions are confined to the pharyngeal lymphatic glands | |
| (d) When the lesions are confined to any combination of the foregoing, but are collectively small in extent | |

In regard to pigs, the Commissioners recommend that the presence of tubercular deposit in any degree should involve seizure of the whole carcass and of the organs. Professor Koch does not share these views: he thinks it undesirable to take any precautions against the spread of tubercle by the agency of meat. His views are, however, not generally accepted by pathologists, and a Royal Commission will no doubt have to examine into the question.

Shell-fish.—Certain of the mollusca, such as oysters, mussels and cockles, may be at times instrumental in conveying enteric fever by virtue of their having been gathered near to sewer-outfalls. These mollusca also give rise now and again to acute poisoning, and sometimes to a form of mixed infection, in which attacks of acute gastritis are followed after some days by a typical attack of enteric fever. Proximity to sewage is probably responsible for some of the acute poisoning, as well as for enteric fever, and it is found that when poisonous mussels are placed in water free from contamination they lose their poisonous properties. Some of the crustacea are instrumental in producing severe and even fatal poisoning. The relation of the food of molluscs and crustaceans to the attacks above referred to has not secured adequate attention.

Wheat-flour and bread.—The chief points are to ascertain that there is no ergot, no fungi, nor acari; that alum has not been used; and that other grains or mineral matter are not mixed with it.

Of *Milk*, the chief falsifications consist in addition of water or removal of cream, and the addition of preservatives such as borax, boric acid, formalin, &c., to milk is a subject which is clearly of no small concern to the sanitarian and to the medical

practitioner. The indiscriminate and unknown employment of substances used as therapeutic agents obviously calls for control, and the matter has quite recently been the subject of an inquiry by a Departmental Committee of the Local Government Board. The Committee will, it is expected, recommend that the use of all chemical preservatives in milk should be prohibited. Milk may also be improper for use owing to the presence of blood, lacteal casts, and pus; and unquestionably it will be dangerous if it have been derived from cows affected with the diseases before mentioned. Although there are no very ready means of discerning this dangerous quality, any risk of specific disease may be much diminished by means of pasteurisation.

Other foods are not often concerned in the production of disease, except in so far as they may have undergone decomposition. Accordingly they less often come under the cognisance of health-officers than of the analysts appointed under the Sale of Food and Drugs Acts. It may be defined as the business of these analysts to determine whether or not an article really is what it professes to be; to detect the presence and amount of foreign substances, or of decomposition and putrefaction; and sometimes to show whether or not a given specimen reaches a certain appointed standard of value. The law permits mixtures to be sold in some cases, if the admixture is stated on a label.

The Preparation and Storage of Food.—More attention should be paid to both these matters. Sanitary Authorities should possess extended powers to examine into the methods of food-preparation, such, for instance, as that of preserved and tinned meats, fish, and fruits, the making of sausages, margarine, &c. The manufacture of beers, wines, and temperance-drinks, as also of the substances used in their preparation and preservation, should be under better control, the recent occurrence of arsenical poison in connection with the consumption of certain beers having amply justified the legislature in taking further steps in this direction (p. 557). The position of larders in respect of freedom from drain-effluvia and contaminated dust is important, as also is the storage of foods in hotels, restaurants, &c.

The Investigation of Illness suspected to be caused by Food.—Inquiries of this nature should be approached in a systematic manner, and it will be found useful in dealing with any given household to make a complete list of every article consumed by each inmate, whether such inmate has been attacked or not. By arranging the information in a tabular form it will be possible to see at a glance what, if any, foods come beneath suspicion and what may be dismissed.

8. *The Regulation of Trades.*—Trades are affected by the law under two aspects: 1st, irrespective of the nature of the particular trade, the *place where it is carried on* is regulated under the Mines, Factories, and Workshops Acts, and by the Public Health Act of 1875. Urban Authorities can make by-laws regulating offensive trades, such as blood- and bone-boiling, fell-mongering, soap-, tallow-, and tripe-boiling, &c. The object of these Acts, among other things (such as restriction of labour at certain ages), is to provide that the common conditions of health are not violated. This is a very necessary point, for many workshops are

deficient in light and air, are badly ventilated, or are rendered unhealthy by gas burnt for light. Many small workshops are owned by men of small capital, who would sacrifice the health of workmen by compelling them to work under very unfavourable conditions. Happily the faults are usually easily remedied by a little common sense and simple appliances, and in this respect the Workshops and Factories Acts have done great good. One special fault in many workshops is, however, still common, namely, the burning of gas in large quantities in dark shops, without proper means of carrying off the products; the very great influence of this condition on the lungs was long ago pointed out by the late Dr. Guy.

2nd. The other point in the regulation of trades is to prevent any of the *processes being nuisances* or injurious to the health either of the workpeople or the inhabitants of the surrounding districts. This is an extremely wide subject. Trades may annoy and inconvenience the public, as by offensive effluvia, black smoke, or acid vapour which destroys vegetation, yet may not be distinctly injurious to health. On the other hand, without being notable nuisances in the above sense, they may be hurtful to health, especially those (and they are very numerous) which give rise to dust in the air of any kind. Cotton and woollen *débris*, filings and grindings, particles of size, clay, dry paints, and many other substances, come under this head. There is no doubt that the inhalation of all solid particles, no matter whence derived, is highly injurious to health. Much debate has taken place as to whether certain gases, such as chlorine, iodine, sulphuretted hydrogen, sulphurous acid, or the foetid vapours given off from catgut, gelatine, manure, and other trades, are or are not injurious to the health of the workmen, or persons living near the factories. In many cases the discussion is not closed, and fuller inquiries are necessary; but at present it seems as if these gases and foetid effluvia, in such proportions as they are met with about factories, are not proved to be unhealthy (though their innocuousness cannot be asserted), however disagreeable they may be. On the other hand, some really dangerous gases, such as carbonic oxide, are not offensive to the smell. Phosphorus-fumes escaping into the air have affected the jaw-bones of persons exposed to them; this happens now much less than formerly, though recent cases are on record, owing in large measure to the increased use of red or 'amorphous' phosphorus in the manufacture of lucifer-matches.

The spread of *infection by trade operations*, as of anthrax among wool-sorters, and of small-pox among paper-makers, has recently come to demand recognition.

There is one article, the sale of which gives rise directly and indirectly to a large amount of sickness, and although the matter is one which has not yet been seriously faced by our hygienists, it is clear that the sale of alcohol in all its forms requires better regulation, if the public health is to be regarded. Owing to peculiar social customs, and to the insufficient recognition of the immense amount of harm produced by excess of alcohol, the laws of this country have not only legalised the sale of a dangerous article of diet, but have actually encouraged the sale, until an evil so gigantic has been produced that no one has yet suggested a reasonable remedy. Yet the sale of alcohol is so

distinctly a source of preventable disease and of injury to the State, that it should be considered by those who have charge of the Public Health, and in some way must eventually be restricted (*see* ALCOHOLISM). One source of the error seems to be that alcohol is regarded by the State, not only as a source of revenue, but as the one indispensable article of 'refreshment.' There is, of course, no question that the public must be supplied with houses where they can obtain proper refreshments, such as meat, bread, vegetables, milk, coffee, tea, or other articles of the kind; and 'public-houses' were intended to supply articles of this description as well as the alcoholic liquids which enter into the ordinary diet of most people. Yet, unfortunately, a system has grown up by which our public-houses have become places where little else than alcoholic liquors are sold, and this system is defended on the ground that such liquids constitute 'refreshments.' The amount of temptation which has been put in the way of our working classes by the heedless multiplication, during the last fifty years, of these drinking-shops, when facilities are not afforded for obtaining the drinks which many persons would prefer to alcohol, accounts for much of the drunkenness which so deeply affects our national life, and injures the health of the people. A remedy ought to and must be found for this state of things, or else legislation will continue to present the absurd spectacle of raising up one huge mischief to the public health, while it is all anxiety to rid the community of every other.

9. *The Arrest and Control of Infectious Diseases.*—Although within recent years considerable progress has been made in our knowledge of the natural history of certain infectious diseases, it has to be accepted that the advances both of epidemiology and bacteriology have taught us that the scope of preventive medicine must needs be much extended if we are to trace the pathogenic bacteria to their several haunts. Were all infectious and contagious diseases confined to the human species, and, moreover, had they no existence outside the animal body, the problem of control would be relatively simple.

Unfortunately for administrative methods, we know that in respect, at any rate, of diseases such as tuberculosis, bubonic plague, anthrax, diphtheria, and many others, the specific organisms maintain their existence not only outside the human economy, but, in certain cases, also outside the animal kingdom. So, too, bacteriology, which is assisting administration by its ability to diagnose such diseases as have been associated with specific micro-organisms, has demonstrated that such specific bacilli may exist in apparently healthy persons, and that in those who have suffered from an attack of infectious disease, the specific organisms may exist long after the attack has apparently passed away. If, therefore, preventive medicine is to reap to the full the harvest of its labours, it must take note of all the conditions making for the survival and multiplication of pathogenic organisms.

Up to the present, the scope of preventive medicine has not been so extended as public opinion may presently demand. Efforts have been made by means of notification, isolation, vaccination, disinfection, and other sanitary measures, to control the spread of disease such as typhus fever, enteric

fever, scarlet fever, diphtheria, small-pox, cholera, plague, and certain others. The prevalence of some of these diseases has been much reduced, of others almost total extinction, for the time being, at least, has resulted; others again have not proved very amenable to the methods adopted. There are, however, other preventable diseases which tax our life and health, but which have not, as yet, been brought fully within the field of preventive medicine. Examples of such diseases are tuberculosis, measles, whooping-cough, and diarrhoea. With contagious diseases such as syphilis and gonorrhoea, the sanitarian of to-day would appear to have little concern, although considerations of the health of the race, and of economy, point to the necessity of further control.

A new branch of preventive medicine has, however, made great strides of late, and it may be that in preventive inoculation we may be able to do much during the advance and presence of certain infectious diseases. The duration of protection afforded by one attack of the diseases in question would hardly lead to the hope that such success will accrue as with vaccination against small-pox, but the indications with respect to diseases such as plague, cholera, enteric fever, &c., lead to the hope that attendants and others who have been exposed to infection may reap therefrom some protective or curative benefit.

The general principles on which the control of infectious diseases is based are—(1) The recognition of the places of origin and conditions of formation of the morbid agent, with recognition, also, of the processes to which it gives rise, alike in structures of the human body and in substances outside and independent of the body, with further question as to the nature of these substances, structures, or processes; the more fully these points are known, the more it is to be expected that the formation of the agent can be prevented or the agent be rendered harmless. (2) The recognition of the means of spread of the agent, after its first formation, that is, whether it spreads directly through the air, and, if so, through what distances and under what conditions; or whether it is carried in drinking-water or in food, or is transferred directly from one person to another: in proportion as this recognition has been gained, the carriage of the morbid agent may be stopped. (3) The early removal of the person affected from among the community, so that the risk of spreading in any way may be lessened. The system of compulsory notification of infectious disease which is now in operation throughout the country has rendered it possible for the local authorities of towns to keep infected children out of schools, and by other like means to limit the opportunities of infection; and also to secure the isolation of infectious cases as they arise or are imported into the town, and thus to diminish the opportunities of infection.

In the case of each of these diseases the preventive measures are different, and it is impossible here to go into so large a subject as the specialities of each. The measures include a continual supervision over the conditions of origin, introduction, and spread, as far as they are known.

Two points must, however, be noted more particularly. The first is the isolation of persons ill with any disease which directly or indirectly can spread from one person to another. In the crowded houses of towns some diseases, such as typhus,

scarlet fever, measles, and relapsing fever, may, at times, spread with great rapidity, and the only means that we at present possess for checking them are to remove the sick at the earliest moment from such houses, and to prevent persons ill with infectious diseases from exposing themselves in public places and conveyances. For this purpose Sanitary Authorities have powers to remove persons ill with infectious diseases to a proper hospital in special conveyances; to prevent sick persons frequenting public places or conveyances; and to deal with infected rooms, houses, and clothing. A hospital for infectious disease should therefore be provided in every locality, its advantages being (a) to minimise the risks of infection from invaded households to the remainder of the community; (b) to enable the sick to be separated from the healthy in the household, and the healthy to proceed with their occupation or education as the case may be; and (c) to provide better medical control and nursing than is practicable in the homes of the poor. These hospitals should be substantially built institutions, placed in attractive and easily accessible situations. Temporary structures of wood and iron are unsatisfactory. The hospital buildings should consist of (a) ward-blocks for the reception of the sick; (b) administrative blocks for the housing of the staff and stores, and (c) out-offices, such as laundry, mortuary, and disinfecting rooms. A discharge-block is a useful addition, as also are separate wards for the treatment of doubtful or very severe cases. The proportion of one bed per 1,000 of the population has been suggested as a working basis, and each bed should have at least 12 linear feet of wall-space, 144 square feet of floor-space, and 2,000 cubic feet of air-space. All surfaces should be as impervious as possible, in order to facilitate cleansing and disinfection. Cases of small-pox, owing to the peculiar tendency of this disease to spread to surrounding buildings, should not be treated in the same hospital with cases of other infectious diseases. Small-pox hospitals should be at a distance from aggregations of population. By means of the Public Health Acts and by the Isolation Hospitals Acts, 1893 and 1901, considerable power is conferred upon Local Sanitary Authorities to erect Isolation Hospitals either separately or jointly.

THE PREPARATION OF THE SICK-ROOM IN A CASE OF INFECTIOUS DISEASE.—All unnecessary furniture, carpets, curtains, bed-hangings, &c., should be removed from a room intended for the isolation of a sick person, a room at the top of the house, or one far removed from the other inmates, being selected. Such a room should be light and well ventilated, and a fire for the burning of infected rags, dressings, &c., and to assist ventilation, should, if practicable, be kept burning. A sheet moistened with some disinfectant may be hung over the door by way, mainly, of impressing upon the inmates the importance of isolation. The attendant upon the sick person should keep aloof from the other inmates and be provided with a room on the same floor and adjoining the sick-chamber. The nurse's room should be disinfected in common with the sick-room.

DISINFECTION.—Every Sanitary Authority should provide thoroughly reliable means for the disinfection of infected articles and dwellings, and should not, by the use of obsolete methods, convey a false sense of security more dangerous than recognised infection. For the disinfection of bulky articles,

such as bedding, carpets, and clothing, the use of one or another steam apparatus is essential. Hot air does not possess the penetrative or bactericidal qualities of steam, and is, moreover, liable to scorch and damage articles exposed to it. There are many forms of steam apparatus on the market, some of which use steam under high pressure, some under low pressure, and others with atmospheric pressure alone. There are certain differences with regard to penetrative power and the duration of time necessary to expose the articles, but it may be said that the cheaper low-pressure machine conforms for the most part to the requirements of efficient disinfection. 'Saturated' steam possesses considerable advantages over 'superheated' steam. But the method which has been adopted in certain machines in which hot air is merely moistened by steam is much inferior to those which rely, as do the apparatus referred to above, solely upon steam. Some articles, such as leather, furs, the binding of books, &c., are spoilt by the use of steam; for these, hot air is far less damaging, and many of the steam apparatus provide for the use of hot air as well as steam—indeed, hot air is in many cases essential for the drying of the articles moistened by steam. The disinfecting building should be divided into two parts, and the machine, which should be fitted with a door at each end, should be fixed in the dividing wall in such a manner that the only communication between the two chambers is through the disinfector. Portable steam disinfectors can now be procured. Although it is established that fresh air and sunlight, more particularly its actinic rays, speedily destroy the virus of certain infectious diseases, such as typhus fever, that of others, of which small-pox may be given as an example, appears to be much more resistant.

Free use should always be made of air and sunlight, but as, in the words of Koch, 'a good disinfectant must be rapid in its action as well as certain,' the use of chemical disinfectants is essential in cases where steam or boiling water cannot be brought into requisition, or the infected articles cannot be burnt. By the term *disinfectant* is understood a germicide (p. 412); the terms *antiseptic* and *deodorant* being applied, respectively, to such agencies as inhibit the growth of organisms or destroy effluvia.

The Disinfection of the Sick-room.—All bedding, carpets, clothes, &c., should be removed in canvas-bags moistened on the surface, and in properly appointed vans, to be disinfected by steam, while articles which can be safely boiled should be submitted to that process, and those which are valueless should be burnt. Before disinfecting or boiling all stains of blood or excreta should be removed by soaking the articles in cold water, otherwise the stains are liable to become fixed. The fumigation of rooms may be carried out by such gases as sulphurous acid, chlorine, or nitrous acid, &c. Sulphurous-acid gas may be generated by burning at least 3 lbs. of sulphur for every 1,000 cubic feet of space, by the use of Kingzett's sulphur-candles, or of sulphurous-acid gas liquefied by pressure, and contained in metal cylinders; the receptacle containing the sulphur being supported over a pail of water placed as high up the room as possible to aid the diffusion of the heavy gas. The air of the room should be previously moistened by steam. Bright metal surfaces are likely to be tarnished by the sulphurous gas, and hence they should, where

practicable, be washed over with a 2-per-cent. solution of carbolic acid, and removed from the room. The efficacy of sulphurous-acid fumigation is, however, somewhat open to doubt.

Within recent years formic aldehyde has been increasingly and successfully used as a gaseous disinfectant, and the aldehyde-vapours may be conveniently liberated from 'formalin,' a 40-per-cent. solution of formic aldehyde, by means of some specially devised apparatus such as that of Trillat, or the formaldehyde may be generated in the 'Alformant' lamp by heating tablets of paraformaldehyde together with the simultaneous production of water-vapour. Care must be taken to use sufficient tablets. In the disinfection of walls and other surfaces use may be made of sprayers, by means of which solutions such as perchloride of mercury, or 'formalin,' may be sprayed in finely atomised forms.

In the fumigation of an infected room, whatever be the gas used, all crevices and openings, including the fireplace, should be papered over, as also should the door by which the disinfectant gains exit. The room should be kept closed for some twenty-four hours, and at the termination of that time be thoroughly aerated; indeed, it is this aeration which is one of the advantages of the fumigation-method, and the additional measures now mentioned should never be neglected. The paper should be stripped from the walls, or, if the nature of the disease does not render this necessary, carefully rubbed over with bread 48 hours old, the ceilings lime-washed, and the floor and all suitable surfaces washed with a disinfecting solution; care being taken to select such disinfectants as will do no damage. Disinfecting solutions may be made of many substances, but perhaps the two most efficient are *acidulated* perchloride of mercury (1 in 1,000), and carbolic acid (5 to 10 per cent.). A useful solution recommended by the Local Government Board consists of: Mercuric chloride, 3 ss; hydrochloric acid 3 j; commercial aniline blue, gr. v; water, 3 gallons. But in the use of any such solution regard must be had to its 'working strength,' i.e. if perchloride of mercury 1 in 1,000 be in question, care must be taken not to make it 1 in 5,000 by adding it to the liquid to be disinfected. All disinfectants should be carefully labelled and kept in characteristic receptacles. In the disinfection of excreta, such as those from a case of enteric fever, it is desirable that the vessel receiving such excreta should contain some of the disinfecting solution, that they shall be intimately mixed therewith, and remain thus mixed for some time. Excreta may, if necessary, be burned after being freely mixed with sawdust and saturated with paraffin. In the case of a body dead of infectious disease, it is a useful precaution to envelop the corpse in sheets saturated with very strong solution of perchloride of mercury or carbolic acid.

10. *The Disposal of the Dead.*—Some 500,000 corpses have to be disposed of annually in England and Wales; and as Sir Henry Thompson has tersely expressed it, the problem is 'Given a dead body: to resolve it into carbonic acid, water, and ammonia, and the mineral elements rapidly, safely, and not unpleasantly.' Two points are involved in the disposal of the dead, both in towns and villages.

In this country, where so many families live in single rooms, and where the custom of keeping the

dead five or even six days before burial is usual, it constantly happens that a corpse is kept for days in the room where all the family life is carried on. As decomposition, especially in some diseases, commences early, it cannot be doubted that an unfavourable effect on health must be often produced. To avoid this detention, mortuary chapels ought to be constructed in all towns and villages, and to these all corpses should be removed from the houses of the poor within thirty-six hours after death.

Power has long been given to Local Authorities to provide mortuaries (in London such provision is compulsory) and to remove, when necessary, corpses from rooms where persons live and sleep. Very little has yet been done in this way, and England is in this respect far behind some of the Continental States.

The other point is the disposal of the corpse. The law of England now allows no burial-grounds in large cities, nor burial under churches, consequently cemeteries are provided at convenient distances from towns. These cemeteries ought to have a dry soil, so that the ground-water shall never rise high enough to wet the corpse or to float it up in the vault, as sometimes has happened; they should be as far from houses as practicable, and a limit of 200 feet is contemplated as a permissible minimum. There should be good drainage to permit a free flow of water, and the water should not run into any well or watercourse from which drinking-water is taken. It has, however, to be stated that the risk of the specific pollution of water-supplies by the drainage of cemeteries is not in practice a very serious one, inasmuch as the life of pathogenic organisms in the dead body is not of long duration. Klein has recently shown that the organism largely concerned with the destruction of the body is an anaerobic bacillus, which he terms *Bacillus sporogenes cadaveris*. The site should be well ventilated and well planted, so that the roots of the plants may absorb the decomposing matters. The kind of soil will, of course, depend on the locality; in many cases there is no choice; but if there be a choice a dry porous soil, such as sand or gravel, allowing free permeation by the air and the moisture necessary to allow the micro-organisms associated with the decomposition of organic matter to do their work, should be chosen. Clay-soils, unless very completely under-drained, are, as pointed out by Dr. C. W. Young in a recent report to the London County Council, ill-fitted for burial-grounds, by virtue of the fact that coffins in such a situation are more or less water-logged, and hence the aeration necessary for proper bacterial action is prevented. Decomposition is indefinitely delayed, the body undergoing saponification and passing into what is known as *adipocere* (p. 27). Moreover, clay-soil, more especially in the case of recently made graves, is liable to crack during dry weather, the cracks at times reaching down to the coffin itself, and affording passages to the gases of decomposition.

The practice of burial which at present obtains, although perhaps in a gradually diminishing degree, of preventing the access of earth to the body by means of coffins of a relatively imperishable character, and by burial in brick graves, is to be condemned. Perishable coffins should be used, and brick graves disallowed.

The present law prevents the burial of bodies of

adults within four feet of the surface; but the researches of bacteriology, as also the results of experience, rather indicate that more superficial burial should be legalised, and deep interment forbidden. A study of the flora of the soil at different depths points to the conclusion that bacteria, many of which are necessary to complete the process of decomposition, are not found below the first few feet of soil, and that deep interment leads to much delay in the resolution of the body.

The more superficial the burial of the animal body, the quicker the decomposition, and the bodies of animals merely covered with a layer of soil a foot thick have—save for their bones—entirely disappeared within a year. But extended observations are desirable before more superficial burial could be generally sanctioned in all conditions of soil and in thickly peopled cemeteries.

With the growth of cities there will come a time when it will be impracticable to accord to each corpse the freehold of its grave, and it will be necessary to adopt 'earth to earth' burial in order that the grave may more speedily be ready for another tenant, or to make a more extended use of the practice of cremation. There are now facilities for cremation at Manchester, Glasgow, Liverpool, Hull, and Darlington, while for London there is a crematorium at Woking, where, during 1900, 301 bodies were cremated. In a properly constructed apparatus a body of average dimensions can be converted into 3 lbs. of ashes in about one-and-a-half hours, and this without nuisance of any description. Obviously the process destroys all risks of the spread of infection, and the ashes are disposed of according to the wishes of the friends.

The chief objection to the process—apart from the weight which may be accorded to sentiment—is the risk that deaths from poison, violence, or criminal neglect may at times escape detection, and it may be contended that the opportunities of exhumation which at present exist act as a deterrent to criminal practices. But a better system of death-registration, together with the production of two medical certificates, and a voucher to the effect that the deceased desired cremation, should do much to reduce the risks of undetected crime.

11. The Supervision of Nuisances.—The word 'nuisance' has been adopted into sanitary law, without any fixed idea of the relation of the word to health or disease. 'Nuisances' are defined as being a number of enumerated conditions, some of which have to be 'injurious to health,' while others need not be injurious to health (but have only to be obnoxious), in order to bring them within the provisions of sanitary law. The confusion thus arising has been such that the primary object of sanitary legislation has sometimes been obscured. So much, indeed, has this been the case that, in comparatively recent times, it has been contended that a given condition which habitually does harm to health, but which had not yet, in the particular instance, succeeded in effecting actual disease, is not a 'nuisance injurious to health' within the meaning of a Public Health Act. With the view of facilitating the administration in this direction, the more recent acts have included under the term 'nuisances' not only those injurious to health but also those dangerous to health.

It is the duty of every Sanitary Authority to cause inspection to be made of their district to

discover 'nuisances,' as enumerated in sanitary statutes; and a certain procedure for the abatement of 'nuisances,' and for the prevention of their recurrence, is appointed by sanitary law. For the performance of these functions the Authority is required to appoint one or more Inspectors of Nuisances, to whose office certain powers are attached.

The work of nuisance-inspection in its everyday concern with conditions injurious to health cannot be properly performed without the constant and intimate relation of the Medical Officer of Health with the Inspector; and those districts are unquestionably best served as to sanitary inspection where the Authority has devolved on the Medical Officer the duty of instructing the Inspector and of supervising his work.

Specialities of Rural Sanitation.—While the objects to be gained by sanitary action are of course the same in town and country, the methods of attaining them in rural places must needs depart in some measure from those which are available in towns; and accordingly sanitary law in its administrative aspects recognises rural as distinguished from so-called 'urban' districts. Rural Sanitary Authorities, constituted in 1872, can now exercise considerable powers; and where properly set in action by their Medical Health Officers and Inspectors of Nuisances, a great effect is being gradually produced upon the rural labouring class, whose condition had long been neglected. The Rural Sanitary Authority may provide water for public use, may make public cisterns or baths, may protect water-courses, may construct sewers and dispose of sewage-matter; must take care that no closet or privy is a nuisance; may clean ditches and remove refuse; and may make regulations as to cellar-habitations and common lodging-houses. Much increased power of securing proper water-supply in the particular house within rural districts has been given, and there are few urban powers which cannot be acquired, if wanted, by any locality that can make a claim for consideration as a 'contributory place.' All powers possessed by urban Authorities as to trades, sale of unwholesome food, removal of nuisances, provision of mortuaries and hospitals for infectious diseases, are now also possessed by the rural authorities.

Although County Councils have in certain instances endeavoured to awaken the people from their lethargy, it must be admitted that comparatively little sanitary progress has been made in rural districts; and unquestionably there are some obstacles, inherent in the case, to any rapid progress. The difficulties arise from the houses in the rural districts being, in a great number of cases, old, dilapidated, unsuited for dwellings, and destitute of proper conveniences. When new houses are built, the Sanitary Authority can enforce certain provisions, though it has less control over building operations than is possessed by urban Authorities. In the case of houses already built, however, its power is, from circumstances, even more limited. There is very little money available for improvements; the poor-rates are already often heavy, and guardians hesitate to increase them. The small number of houses in villages also, in comparison with the outlay needful to supply sewers and water, renders the cost per head much greater than in towns. In addition to bad construction and dampness of houses, the most frequent sanitary defects of

rural places are as follows: The water is too often drawn from shallow wells or from small streams liable to pollution, or even from stagnant pools or ditches, and such supply is limited. Often there are no means for carrying away the dirty house-water, and it is thrown on the ground and soaks into the soil close to and under the cottage; the excreta are generally thrown into an ashpit near the house, or pass into a cesspit, from which they gradually soak, in such way as to pollute both ground and water. These difficulties, however, are being gradually overcome in districts which have secured the services of a first-class Officer of Health, who has sought, by means adapted to the special local conditions, to obtain the same sanitary advantages that are got in town districts by the use of more organised sanitary operations. Attempts are now being made to purify and then to guard the wells; to collect rain-water in proper tanks when other sources are not available; or to store the water collected from the surface-soil of some area secure from drainage, manuring, or like impurities. For the disposal of the slop-water, open or partially closed surface drains leading to ditches, or underground drains that shall allow the water to flow into the soil, and other plans, have been proposed. It is, on any plan, important—but especially if shallow wells or the surface soil is to furnish the drinking-water—to carry off to a distance all the slop-water by drains of some kind. For the removal of excreta (as sewers are frequently out of the question) a pail-system, with or without the use of dried earth or charcoal, according to circumstances, has to be used. If the cottages have gardens, then the simplest dry-earth plan, with proper storage and the subsequent digging into the gardens at intervals of not more than three or four weeks, seems to answer well; yet it is very difficult to get peasants to attend even to this simple matter, and at times, especially if they possess allotments, the excrement is stored up until the season for manuring the land arrives. A plan of conjoint action in the procuring, drying, and distributing the earth, and in the removal of the mixed earth and excreta, answers well when care is taken. In other cases a pail-system, with weekly removals, and without the use of earth or other appliance, has been employed, and may answer, as the manure has some value.

These seem at present the directions in which the opinions of Medical Officers of Health are tending where villages and labourers' cottages are concerned, and where larger works cannot be undertaken. The object, of course, is to obtain for the rural community by simple means, and at not too burdensome a rate, the sanitary requirements of pure soil, of pure air, and of pure drinking-water.

Houses.—Although to some extent the inside of a house is beyond the control of the public health authority, the law takes cognisance of the existence of *nuisance* inside, as well as outside, a house; and has special provisions for securing wholesomeness of habitation in the following cases:—

1. *Common lodging-houses* have been regulated since the great Public Health Act of 1848, the authors of which were evidently profoundly impressed with the great evils of overcrowding. The definition of a common lodging-house that is now usually accepted is that given by the law officers of

the Crown in 1853—namely, a house in which persons of the poorer class are received for short periods, and, though strangers to one another, are allowed to inhabit one common room. These houses are registered and inspected; the number of lodgers is fixed; and ventilation, cleanliness, and water-supply are now attended to. A certain cubic space per head in the sleeping-room of these houses is generally fixed by the authority, the minimum amount suggested by the present Model By-laws of the Local Government Board being 300 cubic feet for each adult, every two children under the age of ten years being counted as one lodger. If the rooms are not used exclusively as sleeping apartments, the models give 400 cubic feet for adults, and 200 cubic feet for children.

2. *Cellar-habitations.*—Since 1848 it has been unlawful to use cellar-habitations, unless they are in accord with certain conditions of space, height, window-area, and drainage. By the Public Health Act of 1875 it is made unlawful to use any cellar as a dwelling (that is, a place where any person passes a night) which has been built or rebuilt after the passing of the Act, or which was not lawfully in use when the Act was passed. A cellar is defined by various statutes to be any room of a house, the surface of whose floor is more than three feet below the surface of the footway of the adjoining street; and it has to fulfil a number of conditions before it can be legally inhabited. These conditions are, as regards London, somewhat modified by the Public Health (London) Act, 1891.

With the supervision that has been given to common lodging-houses during recent years, they have become much healthier and more decent habitations. Similarly the number of cellar-dwellings in our towns has much decreased, and the condition of those still used has notably improved.

3. '*Houses let in lodgings*,' or occupied by members of more than one family, are distinguished from common lodging-houses, and would more conveniently be termed *tenemented* houses. Sanitary authorities have various important powers conferred on them in respect of this large class of houses where two or more families live in the same house. But, for these powers to be brought into operation, the consent of the Local Government Board is required.

4. *Overcrowding.*—This condition, so dangerous to the health of the inmates, is to be regarded—no matter in what house it is observed, or whether the inmates be of the same family or not—as a nuisance, and is to be dealt with as such. The question arises, what is overcrowding, and usually the common lodging-house rules are taken, namely, an air-space of 300 cubic feet per head. But there is no legal definition, except in Scotland, where the General Improvement and Police Act of 1862 enacts that children under eight years of age shall have 150 cubic feet, and persons over that age 300. Obviously, the standard of space per person adopted as the minimum in the *bedrooms* of common lodging-houses, where the occupation is by night only, is too small for those who have to occupy the same room both by day and night, as is usually the case, where the question of overcrowding arises in the dwellings of the poor. It would be very desirable to raise the minimum (at all events for persons over ten years) to 400 cubic feet, and this is really little enough.

Causes of Unhealthiness of Houses.—

1. *Dampness*.—Dampness arises from a damp soil, water rising into walls, rain beating through walls or coming from a leaking roof, or blocked water-pipes. Paving, concreting, damp-proof courses, hollow walls, impermeable surfaces, &c., are the remedies. Damp houses are unhealthy, it would appear, by reason of the lowering of warmth conducing to catarrhal and rheumatic affections, and possibly by reason of increased bacterial life due to the constant presence of moisture.

2. *Excessive coldness of air from draughts, or from insufficient warming*.—Although an airy house is the healthiest, there may be excessive or irregular movement of air, so that strong currents are caused, with consequent undue skin-evaporation; whereby the body-temperature may be lower than is good for health, even if persons are well-clothed. The draughtiness is matter of construction, and is obviated by improvement in the methods of ventilation. Then, as to warming. Our present English use of fireplaces is both inefficient and expensive. It might have been expected that, in towns, this plan of warming houses would long ago have been abandoned for some more general use of hot-water or steam pipes. The supply of warmed fresh air is a very simple proceeding when these pipes are used, and thus not only can houses be better warmed, but better ventilated and less draughty. The greater convenience of a furnace serving to heat several houses is not at present appreciated in England; but here and there this consideration has probably contributed to the use of 'flats' in place of separate houses.

3. *Impurity of the air*.—This arises from the following conditions: from the air being drawn from the ground into the house, or passing over impure earth or deposits; or by the air in the house becoming contaminated by effluvia from closets and drain-pipes; from combustion; from respiration and skin-transpiration; from uncleanness of persons, clothes, walls, floors, and furniture.

Each of these conditions has to be examined into and rectified according to the usual principles laid down in works of hygiene. A few remarks may, however, be permitted on some of the headings.

The removal of respiratory impurities can only be accomplished by constantly removing the air of rooms and supplying fresh air. This is *ventilation*; and, if we include in the definition that the supply and removal of air shall be tolerably uniform, ventilation presents a mechanical problem of no little difficulty. The amount of air required for an adult, in order to keep the air relatively pure, has been fixed at 3,000 cubic feet per hour; or if the carbonic acid derived from respiration be taken as a measure of respiratory impurity, it should not exceed .2 per 1,000 volumes of air. Practically, the amount most persons get is not more than 600 to 1,200 cubic feet per hour, if so much, and the air of their rooms smells fusty from organic effluvia. In cold times of the year, the entering air must be warmed, if the change is to be so rapid as is implied in the supply of 3,000 cubic feet of air per hour, equivalent to a change of air in the air-space three, four, or even five times per hour. When warmed to nearly the temperature of the surface of the body (80° to 90° F.) considerable movement of air is borne without difficulty, but if the temperature be much lower a correspondingly slighter movement is felt. Ventilation in this climate is therefore inextricably

mixed up with warming, and thorough ventilation of our rooms is impossible so long as we trust to radiant heat alone for warmth. The problem, therefore, which engineers have to solve in warming and ventilating our rooms is, what is the cheapest and most constant plan of introducing warm air into our houses in cold weather; the conditions of the problem being a supply of 3,000 cubic feet per head per hour, at a rate of movement imperceptible to the feelings of the persons in the room.

The second point is connected with the impurity of the air from drains. The first thing is to be certain that the air of the house-drain is so thoroughly disconnected from the air of the public sewers that no reflux from them is possible; and therefore, that, if there is any drain-air polluting the atmosphere of the house, it is not the air of the common sewer. That point having been settled, it will follow that drain-smell in the house must come either from the ground or from the house-pipes or closets themselves. If from the ground, there is probably (if the ground itself be clean, or if the smell be of new production) a leaky drain-pipe somewhere, and the air is penetrating through the leakage and is drawn into the house. If not from the ground, the smell may be from some pipe in the house; this arises from imperfect junction, especially when metal pipes are joined on to earthenware, or from the pin-hole eating-away of metal pipes. Or a drain-pipe may be choked (generally through 'settling' at a joint occurring in an ill-laid and badly bedded pipe), and decomposition be going on in its retained contents. Or there may be a clogged or imperfect trap, with the water either sucked out of it or becoming thoroughly charged with fetid effluvia. In the latter cases, there is a presumption that the ventilation of the house-drain is not what it should be. Every house should have a plan of its drainage, so as to facilitate the search for a broken pipe.

In order to detect any of these conditions it is necessary that builders should alter their habits in regard to house-plumbing arrangements. At present they try to conceal everything, so that, without pulling a house to pieces, it is impossible to examine if pipes and traps are in order. Instead of this, every pipe above the ground should be kept out of walls; and if cased with wood, the case should be merely bolted, and not nailed. If a drain must be carried under a house, it should have inspection-chambers built upon it at every change of direction, so that the drain, which runs in a straight line from one manhole chamber to the next can be inspected and cleared of obstructions or deposit without breaking into it. The sewage and foul-water arrangements of our houses will never be satisfactory till these matters are attended to, and till the examination of every pipe about the house can be made without difficulty, and clogging or leakage of air or water from pipes can be readily detected.

In closets, the chief points of leakage are in the more horizontal pipes and in the traps. In all cases the soil-pipe should be ventilated by pipes carried to the open air at some points away from windows.

Another matter to be guarded against, whether there be drain-smell or not about a house, is the immediate opening of the cistern overflow-pipe, or of the usual rain-water pipe, into the sewer or house-drain. A common practice, until recently, was to connect them directly with the house-drain,

perhaps with an S-trap at the foot of each pipe, these traps, however, being usually dry. Then sewer-air passes up and enters the cistern, or into rooms which happen to be near the top of the rain-water pipe. All these pipes should open in free air over a grating; and if every householder would insist on the builder attending to these matters, the chances of inflow of sewer-air into houses would be much lessened.

Another, third, point of importance is the way in which the products of gas-combustion are allowed to pass into the air of rooms. Nothing can be worse than the usual arrangement; and, as gas-lights might be made a valuable means of ventilation if tubes were arranged to carry off the burnt gas, the present arrangement of chandeliers is not only hurtful, but involves an ignorant waste of useful force.

4. *Impurity of the water.*—Water delivered to a house may become impure on the premises, usually from uncleaned uncovered cisterns, absorption of air from drains by the surface of the water, and sometimes by more direct leakage from pipes into cisterns. Lead may also be taken up. The remedies for these conditions are obvious. Reference has also been made to extensive epidemics of enteric fever due to the insuction of matter from sewers into public water-pipes, through fissures in those pipes while running full. It is possible that obscure cases of disease in particular houses are sometimes due to an unsuspected pollution by similar means of the water-service of the house.

5. *Impurities from uncleanness of the house.*—Walls and ceilings all absorb impurities which are given out again to the air, and often become highly impregnated with organic matters. The chinks of floors allow matters to collect below them, and then impure air rises into the room.

The custom of re-papering walls without removing the old paper, the decomposition of paste and paper on damp walls, and the use of arsenical pigments, may give rise to impurities of one and another kind in the air of houses. In the houses of the poor which are not regularly whitewashed, the half-crumbling plaster is often highly charged with animal material.

These matters are to be avoided by original good construction and by constant cleanliness. It is a great desideratum to make walls of impermeable material, so that they may be washed without difficulty.

If these various points, which are really questions of purity of air and water, and of temperature and movement of air, are properly dealt with, houses will be healthy. These are conditions which are not difficult to secure if they are clearly understood and if their importance is not underrated. The great point is to have the house-air pure, so as in no way to injure or depress the great function of respiration.

While we look to the Municipality or Local Sanitary Authority to keep the outer air pure, the task of doing the same for the house-air must necessarily fall on the inhabitants of the house.

Duties of the Medical Officer of Health.—It behoves the residents of every district to assist the Sanitary Officers to the best of their ability; and to aid towards such endeavours, this article may usefully conclude by an enumeration of the duties which are imposed upon the Medical Officer of Health for districts in England. They are

extracted from an order of the Local Government Board, dated 1891.

‘The following shall be the duties of the Medical Officer of Health in respect of the district for which he is appointed :—

‘1. He shall inform himself as far as practicable respecting all influences affecting or threatening to affect injuriously the public health within the district.

‘2. He shall inquire into and ascertain by such means as are at his disposal the causes, origin, and distribution of diseases within the district, and ascertain to what extent the same have depended on conditions capable of removal or mitigation.

‘3. He shall by inspection of the district, both systematically at certain periods, and at intervals as occasion may require, keep himself informed of the conditions injurious to health existing therein.

‘4. He shall be prepared to advise the Sanitary Authority on all matters affecting the health of the district, and on all sanitary points involved in the action of the Sanitary Authority; and in cases requiring it, he shall certify, for the guidance of the Sanitary Authority or of the Justices, as to any matter in respect of which the certificate of a Medical Officer of Health or a Medical Practitioner is required as the basis or in aid of sanitary action.

‘5. He shall advise the Sanitary Authority on any question relating to health involved in the framing and subsequent working of such by-laws and regulations as they may have power to make, and as to the adoption by the Sanitary Authority of the Infectious Disease (Prevention) Act, 1890, or of any section or sections of such Act.

‘6. On receiving information of the outbreak of any contagious, infectious, or epidemic disease of a dangerous character within the district, he shall visit without delay the spot where the outbreak has occurred, and inquire into the causes and circumstances of such outbreak; and in case he is not satisfied that all due precautions are being taken, he shall advise the persons competent to act as to the measures which may appear to him to be required to prevent the extension of the disease, and take such measures for the prevention of disease as he is legally authorised to take under any statute in force in the district, or by any resolution of the Sanitary Authority.

‘7. Subject to the instructions of the Sanitary Authority, he shall direct or superintend the work of the Inspector of Nuisances in the way and to the extent that the Sanitary Authority shall approve, and on receiving information from the Inspector of Nuisances that his intervention is required in consequence of the existence of any nuisance injurious to health, or of any overcrowding in a house, he shall, as early as practicable, take such steps as he is legally authorised to take under any statute in force in the district, or by any resolution of the Sanitary Authority, as the circumstances of the case may justify and require.

‘8. In any case in which it may appear to him to be necessary or advisable, or in which he shall be so directed by the Sanitary Authority, he shall himself inspect and examine any animal, carcase, meat, poultry, game, flesh, fish, fruit, vegetables, corn, bread, flour, or milk, and any other article to which the provisions of the Public Health Act, 1875, in this behalf shall apply, exposed for sale, or deposited for the purpose of sale or of preparation for sale, and intended for the food of man,

which is deemed to be diseased, or unsound, or unwholesome, or unfit for the food of man; and if he finds that such animal or article is diseased, or unsound, or unwholesome, or unfit for the food of man, he shall give such directions as may be necessary for causing the same to be dealt with by a Justice according to the provisions of the statutes applicable to the case.

'9. He shall perform all the duties imposed upon him by any by-laws and regulations of the Sanitary Authority, duly confirmed where confirmation is legally required, in respect of any matter affecting the public health, and touching which they are authorised to frame by-laws and regulations.

'10. He shall inquire into any offensive process of trade carried on within the district, and report on the appropriate means for the prevention of any nuisance or injury to health therefrom.

'11. He shall attend at the office of the Sanitary Authority or at some other appointed place, at such stated times as they may direct.

'12. He shall from time to time report in writing to the Sanitary Authority his proceedings, and the measures which may require to be adopted for the improvement or protection of the public health in the district. He shall in like manner report with respect to the sickness and mortality within the district, so far as he has been enabled to ascertain the same.

'13. He shall keep a book or books, to be provided by the Sanitary Authority, in which he shall make an entry of his visits, and notes of his observations and instructions thereon, and also the date and nature of applications made to him, the date and result of the action taken thereon, and of any action taken on previous reports; and shall produce such book or books, whenever required, to the Sanitary Authority.

'14. He shall also make an annual report to the Sanitary Authority, up to the end of December in each year, comprising a summary of the action taken, or which he has advised the Sanitary Authority to take, during the year, for preventing the spread of disease, and an account of the sanitary state of his district generally at the end of the year. The report shall also contain an account of the inquiries which he has made as to conditions injurious to health existing in the district, and of the proceedings in which he has taken part or advised under any statute, so far as such proceedings relate to those conditions; and also an account of the supervision exercised by him, or on his advice, for sanitary purposes over places and houses that the Sanitary Authority have power to regulate, with the nature and results of any proceedings which may have been so required and taken in respect of the same during the year. The report shall also record the action taken by him, or on his advice, during the year, in regard to offensive trades, to dairies, cow-sheds, and milk-shops, and to factories and workshops. The report shall also contain tabular statements (on forms to be supplied by us [Local Government Board], or to the like effect) of the sickness and mortality within the district, classified according to diseases, ages, and localities.

'Provided that, if the Medical Officer of Health shall cease to hold office before the thirty-first day of December in any year, he shall make the like report for so much of the year as shall have expired when he ceases to hold office.

'15. He shall give immediate information to us of any outbreak of dangerous epidemic disease within the district, and shall transmit to us a copy of each annual report and of any special report. He shall make a special report to us of the grounds of any advice which he may give to the Sanitary Authority with a view to their requiring the closure of any school or schools, in pursuance of the Code of Regulations approved by the Education Department, and for the time being in force.

'16. At the same time that he gives information to us of an outbreak of an infectious disease, or transmits to us a copy of his annual report or of any special report, he shall give the like information or transmit a copy of such report to the County Council or County Councils of the county or counties within which his district may be situated.

'17. In matters not specifically provided for in this Order he shall observe and execute any instructions issued by us, and the lawful orders and directions of the Sanitary Authority applicable to his office.

'18. Whenever we shall make regulations for all or any of the purposes specified in section 134 of the Public Health Act, 1875, and shall declare the regulations so made to be in force within any area comprising the whole or any part of the district, he shall observe such regulations, so far as the same relate to or concern his office.'

These duties have been considerably augmented by the provisions of subsequent Acts of Parliament; such, for instance, as the Factory and Workshops Acts.

H. TIMBRELL BULSTRODE.

PUERILE (*puer*, a boy).—This word is associated in medicine with the respiratory murmur when it is exaggerated, possessing the characters heard over the lungs in a healthy child. See PHYSICAL EXAMINATION.

PUERPERAL DISEASES.—The diseases associated with parturition, which fall for consideration in the present article, are: (1) Puerperal Convulsions; (2) Puerperal Fever; (3) Puerperal Peritonitis; and (4) Puerperal Embolism and Thrombosis of the Pulmonary Artery. Certain other pathological conditions of equal importance, occurring during the puerperal state, are more conveniently discussed under their several special names. See PELVIC ABSCESS; PELVIC CELLULITIS; PELVIC PERITONITIS; and PHLEGMASIA DOLENS. Puerperal insanity is described in the article INSANITY, Varieties of.

1. Puerperal Convulsions.—SYNON.: Puerperal Eclampsia; *Eclampsia Gravidarum*, *Parturientium*, *vel Puerperarum*; Fr. *Convulsions des Femmes Enceintes et en Couche*; Ger. *Eklampsie in der Schwangerschaft und im Wochenbett*.

DEFINITION.—A peculiar kind of epileptiform convulsions, characterised by loss of consciousness and sensibility, together with tonic and clonic spasms; occurring in the later months of pregnancy, during labour or after delivery, and directly connected with these states; and causing great danger to the lives of both mother and child.

ÆTIOLOGY.—Two conditions which favour the occurrence of eclampsia are: (1) a first pregnancy, and (2) the presence of twins *in utero*. The pathology of the condition is by no means certain, and it is therefore not surprising to find that numerous theories have been brought forward to explain its

causation. The frequent association of this disorder with albuminuria had till lately given rise to the belief that it is the result of uræmia; but numerous cases have been observed in which albumen was present in the urine in large quantity without convulsions occurring. Cases too have been recorded in which no albumen was found in the urine, but it is probably present in every case, although owing to its rapid appearance and disappearance it may not be found at the particular time the urine is examined.

The toxæmic theory of eclampsia is the one that has most supporters at the present day. It has been shown that in women suffering from eclampsia the toxicity of the blood-serum is increased, and the toxicity of the urine is proportionately diminished, and it has also been shown that in these patients there is a period after the cessation of the fits when the toxicity of the urine is again increased. These facts tend to prove that there is an accumulation of certain toxins in the blood of eclamptic patients. During pregnancy the presence of the fetus calls for increased metabolism on the part of the maternal tissues, and this is of necessity accompanied by an increased production of excrementitious matters. In a perfectly healthy woman the liver and kidneys are capable of dealing with such an excess. If, however, for some reason the functions of the liver are, for the time being, interfered with, it may be assumed that various toxic matters will pass into the circulation unchanged and with their virulence undiminished. The presence of albumen in the urine may be regarded as one result of the action of some such poison upon the renal epithelium, and the accompanying interference with the excretory functions of the kidneys will lead to a further accumulation of these toxic bodies in the blood of the patient. A point will at length be reached at which there is present a sufficient quantity of these poisons in the blood to set up convulsions and coma. Such a view is supported by the fact that the changes in the kidneys are frequently similar to those seen in patients dying of acute infectious diseases, and that Bouchard has isolated from the urine substances capable of producing convulsions and coma when injected into animals. The exact nature of the poisons, the seat of their formation, and whether this is in every case within the body, is uncertain. That the poison is not urea has been shown by Bradford, who has demonstrated that there is no excess of this substance in the blood or in the tissues of patients dying of eclampsia. It has been suggested that it is the product of the growth of an organism, but there is not sufficient evidence to support such a view.

SYMPTOMS.—Puerperal eclampsia is happily not of common occurrence, its estimated frequency being about once in 500 cases. The studies of Goldberg show that the disease appears first in about 21 per cent. of the cases during pregnancy, in 56 per cent. during labour, and in 22 per cent. during the puerperium. Occasionally the outbreak occurs without warning, but usually there are premonitory symptoms. The most frequent of these is oedema of the feet and legs, which may extend to the vulva, abdomen, face, and upper extremities, and should at once suggest an examination of the urine, which will almost invariably be found to contain albumen in more or less quantity, with a diminution in the total quantity of urine and in the amount of urea which should be excreted. The

specific gravity is high, and sometimes casts may be found. Other premonitory symptoms are headache, generally frontal, but occasionally limited to one side; epigastric pain or vertigo; loss of memory; and derangements of vision, such as amblyopia, diplopia, and flashes of light before the eyes.

When the convulsive seizure occurs it cannot be mistaken. The eyes first become fixed, and rapid contraction of the muscles of the face occurs, with rolling of the eyeballs, the pupils being lost under the upper eyelids. The face becomes turned first towards one shoulder, then towards the other. The convulsions rapidly extend to the other parts of the body; after a short period of tonic contraction violent clonic spasms occur. The face becomes livid, the tongue is protruded, and, if care be not taken, it is lacerated by the teeth, colouring the frothy saliva which is emitted at the angles of the mouth. The thumbs become clenched in the palms, and violent jerkings of the arms occur, while the muscles of the face give rise to a variety of contortions. Sometimes involuntary evacuations of the bladder and rectum occur during the fit. There is total loss of consciousness and sensation. After a few minutes the symptoms gradually subside; a longer interval occurs between the clonic muscular contractions; the face loses its lividity; and the breathing becomes more tranquil. When the first fit has passed off, the patient may recover her consciousness; but if another occur with rapidity, and very little time elapse between the paroxysms, complete coma resulting in death may soon supervene. Where there is a considerable time between the attacks, it may be many hours or days before consciousness is restored, and recovery takes place. A remarkable feature of this disorder is that when the patient becomes sensible, and is restored to health, she has invariably no recollection of what occurred, not only during her illness, but for some time preceding the fits.

PROGNOSIS.—This depends upon the severity and frequency of the paroxysms. It is generally considered that about 20 per cent. of the mothers die. The earlier the convulsions appear in labour, the more unfavourable the prognosis. The longer the labour and the more difficult the delivery, the deeper is the coma and the less the prospect of recovery. In about 30 to 40 per cent. of the cases in which the fits begin during labour, they persist after delivery. In cases beginning after the child is born, the mortality is not more than 12 per cent.

MORBID ANATOMY.—Almost any variety of change may be found in the kidneys. In many cases the renal epithelium shows signs of acute degeneration, such as is seen in patients dying from septicæmia. In the liver the most frequent condition is the occurrence of hæmorrhages, with degeneration of the liver-cells, and the formation of minute necrotic areas. Hæmorrhages, no doubt due to the convulsions, are often found in the lungs and the spleen.

TREATMENT.—Recognising that 'prevention is better than cure,' we must first consider what is best to be done when premonitory symptoms arise. The occasional examination of the urine of pregnant women should always be carried out, and is urgently called for whenever oedema of the feet or other parts is noticed. Slight traces of albumen are not infrequent, and are of no importance; but persistent albuminuria to any considerable amount

requires most careful watching and treatment, and the amount of urea passed in the twenty-four hours should be ascertained. A strict milk-diet, and the administration of diuretics and iron, with hydragogue purgatives, should be tried; but, if little or no improvement takes place, premature labour should be induced, since it gives very good results in these cases. When convulsions occur, there are two objects to be aimed at—the lessening of the irritability of the nervous system, and the elimination of the poison from the body. Since the latter has possibly an intestinal origin, free purging should be at once procured by the administration of croton oil. The patient is to be placed in a hot-air- or vapour-bath, and kept in this until she perspires freely. If the power of swallowing is present, some hot brandy and water may be administered, but if she be unconscious, no attempt should be made to give stimulants or food except through a stomach-tube. Venesection to the extent of thirteen to fifteen ounces of blood may be practised if the patient be not very anæmic or feeble (*see* VENESECTION). Normal saline solution (*see* SALINE SOLUTION, Infusion of) should then be introduced into the vein to the amount of several pints. The object of this ‘treatment’ is to get rid of the venesection of a certain amount of the poison, and by the introduction of the saline solution to so dilute the remainder as to render its elimination by the skin and kidneys more probable. The combination of ‘infusion’ with venesection meets many of the objections urged against the employment of the latter alone. The results of this mode of treatment are encouraging. To lessen the irritability of the nervous system, the best drug is morphine. Half a grain may be given hypodermically, and if the fits continue or the patient remains restless, further doses of $\frac{1}{4}$ gr. may be given every half-hour or so. Veit has administered in this way as much as 3 grs. of morphine within four to seven hours.

If the patient be not comatose or under the influence of the morphine, chloroform should be given while any manipulations are being carried out, or until the morphine has had time to produce its effect, but the prolonged administration of chloroform should be avoided, as it is not without danger.

When the patient is completely comatose and no fits are occurring, neither morphine nor chloroform need be given. In such cases reliance must be placed upon baths, venesection and ‘infusion.’ If the patient be so feeble or anæmic as to render the practice of venesection too dangerous, it must be omitted, but even in such a case benefit may be derived from the subcutaneous injection of saline fluid (*see* HYPODERMIC MEDICATION). Pilocarpine should be avoided, and morphine acts more certainly and speedily than chloral hydrate or potassium bromide. These latter drugs, however, given either by the mouth or by the bowel, are used by many practitioners who are not satisfied as to the safety of administering morphine in these cases.

The patient must be guarded against injuring herself during the fits. Labour should be allowed to proceed naturally, only such aid being given as can be rendered without unduly disturbing the patient. *Accouchement forcé* should never be practised. For the convulsions occurring after delivery the administration of morphine is usually sufficient.

2. **Puerperal Fever.**—SYNON.: Child bed Fever; Puerperal Septicæmia; Surgical Septicæmia; Fr. *Fièvre Puerpérale*; Ger. *Puerperal-fieber*; *Kindbettfieber*.

DEFINITION.—A continued fever of a contagious character, occurring in connection with childbirth.

PATHOLOGY AND ETIOLOGY.—Numerous theories and hypotheses have been suggested in regard to the nature and relations of puerperal fever, or puerperal septic infection, but it is now generally accepted that it is the same disease as surgical septicæmia, occurring in a puerperal patient. It must be distinguished from *sapremia* or *septic intoxication*, in which the patient suffers from poisoning by the absorption of the chemical products of putrefaction, the decomposing material being generally retained portions of membranes or placenta. Puerperal infection is due to the entrance into the patient's body of certain organisms and their multiplication in the blood, in the tissues, or in both.

The organism that most commonly causes the disease is the *Streptococcus pyogenes*, but in some of the cases other organisms have been found either alone or in association with the streptococcus. The commonest of these are the *Staphylococcus albus*, *S. aureus* and *S. citreus*, the *Gonococcus*, the *Bacillus coli communis*, the *Pneumococcus* and the *diphtheria-bacillus*. The genital canal of the healthy woman may be considered as containing no pathogenic or disease-producing organisms. It is possible, however, that under certain conditions the non-pathogenic organisms which are present may attain an increased virulence, and by invading the tissues lead to a general infective process. Such an explanation may account for the very uncommon cases of so-called autogenetic septicæmia occurring in patients who have not been exposed to any possibility of local infection. In a few cases the poison is derived from some local source such as the rupture during labour of a suppurating ovarian cyst or of a pyosalpinx. It is quite certain, however, that in the great majority of cases the patient is infected by the fingers of the attendants, by the instruments used, or by contact with infected fomites.

The virus usually enters the body through the placental site, but it may find its way through any of the lesions in the cervix, vagina, or perineum resulting from labour. The actual sources of the contagion are other cases of puerperal fever, infected wounds, cases of erysipelas, the throat in cases of scarlet fever, the *post-mortem* room and the dissecting room. A patient who is suffering from *sapremia* or *septic intoxication* is very likely to acquire general septic infection, and the disease is also predisposed to by extensive injuries to the soft parts, by exhaustion from prolonged labour or hæmorrhage, by grave emotional disturbances, and by exposure either to cold or to poisoning by sewer-gas. Besides her liability to these general predisposing causes, the parturient woman is specially prone to septic infection because of the deep situation of the wounds in the genital canal, and because of the excessive development of the veins and lymphatics in the wall of the pregnant uterus.

ANATOMICAL CHARACTERS.—After its introduction at some raw surface the virus may invade the body generally either through the veins or the lymphatics, giving rise to the so-called venous or

lymphatic forms of septicæmia. In very acute cases death may occur without the development or any local lesion. More commonly, however, acute inflammatory affections of some part of the genital tract are present. If the vagina be involved, its mucous membrane is red, congested and swollen, and ulcers covered with diphtheritic membrane may be present either in the vaginal walls or in the cervix. The walls of the uterus are soft and oedematous, the mucous membrane is often sloughing, and covered with greyish-red debris, numerous cocci are present in the mucous membrane and the muscular tissue. They may invade the peritoneal cavity though the Fallopian tubes, setting up salpingitis and peritonitis, or directly through the lymphatics and veins of the uterine wall. Small miliary abscesses are often met with, due to the presence of pus in the veins and lymphatic spaces. In the very acute cases of infection by the streptococcus the mucous membrane of the uterus is very little altered, and may feel quite smooth to the examining finger. The pelvic cellular tissue frequently becomes affected. The peritoneum is almost certainly involved, and a coagulated exudation or fluid pus is found in the folds around the uterus, in Douglas's pouch and elsewhere, or the peritonitis may be diffuse, and associated with pleurisy and pericarditis and effusions into the joints. If the absorption has taken place through the veins, broken-down thrombi will be found, and from these embolic pyæmic foci and abscesses may occur in the lungs; the spleen is almost always enlarged, and embolic infarcts may be found in it, as well as in the kidneys. Endocarditis and meningitis may arise; and sometimes, though rarely, septic panophthalmitis and destruction of the eyeball.

SYMPTOMS.—In no disease do the symptoms vary more than in puerperal fever, depending upon the violence of the fever, and the localities attacked by the poison. The fever generally originates within four days after delivery, though sometimes later, very rarely after the fifth day. Occasionally there is insomnia and restlessness preceding the rise of temperature, or a feeling of depression, with headache; or often the first symptom is a rigor. In cases of *sapremia* or septic intoxication the temperature may be only slightly elevated to 101° or 102° . In most of the acute cases of septic infection there is a sudden, rapid rise, accompanied by a rigor, the temperature reaching 104° or 105° . It may be maintained at a uniformly high level, the initial rigor not being repeated, or marked oscillation and frequent rigors may occur. These usually accompany the formation of secondary pyæmic foci. The pulse becomes rapid and feeble, 130 or more per minute. It is often a better guide to the patient's condition than the temperature, since the latter in some of the most fatal cases may be hardly above the normal, or even below it. The skin is generally hot and dry, and fugacious scarlatiniform rashes may appear. Vomiting frequently occurs early, the ejecta being like coffee-grounds, and of a peculiar odour. Diarrhoea is often very troublesome, and the evacuations are horribly fetid. The tongue soon becomes coated with a heavy fur, later on becoming dry and rough; and sordes appear on the lips. There is often acute pain in the abdomen, with tenderness and swelling; but peritonitis with effusion may occur without any of these symptoms. Sometimes the tender, sub-involved uterus can be felt in the hypogastrium.

The lochia are generally suppressed, and the secretion of milk arrested, though sometimes the mammae are hard and painful. If present, the lochia are in some cases very offensive and in other cases quite free from odour.

The spleen is frequently enlarged and easily felt. As a rule, the intellect is unimpaired, though low muttering delirium frequently precedes death. The breathing is short and hurried. Pneumonia, pleurisy, or pericarditis occasionally ensues. Jaundice or albuminuria may be present. The joints may swell and suppurate; and abscesses may form in any part of the body.

COURSE AND TERMINATIONS.—The disease, if of the lymphatic variety, begins very early, and generally runs a rapid course, terminating fatally within a week. The pulse becomes more and more rapid and feeble; the breathing more hurried and panting; tympanites sets in; a cold clammy sweat breaks out; finally hiccough, subsultus, and low muttering delirium come on, with frequently incessant vomiting; and the patient sinks from exhaustion. The venous variety generally shows itself much later, is of much longer duration, and is associated with erratic rigors, and an absence of abdominal distension.

DIAGNOSIS.—A marked rise of temperature within the first week after delivery is usually due to septic infection; other possible causes are constipation, mastitis, the onset of some acute illness, such as pneumonia, or emotional disturbance in a neurotic patient.

The diagnosis between septic intoxication and septic infection can usually be made by discovering retained and decomposing portions of placenta or membranes *in utero*, and by the fall of temperature and rapid recovery of the patient which follow their removal.

TREATMENT.—(1) *Prophylactic.*—This is of the greatest importance. How successfully it can be carried out is shown by the results obtained at the present day in Lying-in Hospitals. In these institutions, which, in the pre-antiseptic days, were hot-beds of puerperal fever, and exhibited in many instances a mortality so excessive that they had to be closed, under modern conditions it is the rarest possible thing for a case of septic infection to occur. In view of the fact that the poison is almost always introduced into the patient's body from without, it is necessary to ensure that everything that comes in contact with the patient is *surgically clean*. At the commencement of labour the woman's vulva, thighs, buttocks, and the lower part of the abdomen must be carefully washed with soap and water. Before any internal examination is made the vulva must be sponged over with some antiseptic solution, such as 1 in 1000 perchloride of mercury. The doctor and the nurse on every occasion before touching the patient's genitalia must thoroughly wash their hands with soap and water, and then scrub them in an antiseptic solution, such as 1 in 1000 perchloride of mercury. Sponges should never be used, wool-swabs wrung out of an antiseptic lotion being employed instead. All instruments, which should be constructed entirely of metal or glass, must be sterilised before use by boiling. Glycerine of perchloride of mercury 1 in 1000, or carbolised vaseline, should be used as a lubricant. Failing either of these the finger may be anointed with a piece of soap the outer layer of which has been washed

off. Cold cream, or lard, or dirty vaseline must not be used. Vaginal examination must be made as infrequently as possible, abdominal palpation being practised instead. Since the genital canal of the healthy woman contains, as a rule, no disease-producing organisms, vaginal douches need not be employed either before, during, or after labour, except under special circumstances. If, for instance, there be a profuse purulent discharge, and a suspicion of gonorrhœa, a douche should be given to diminish the risk of ophthalmia neonatorum. Special care must be taken that no portion of placenta or membranes be retained *in utero*, and if this occur it must at once be removed with the finger. Attention should be paid to the patient's general health so that she may enter upon labour under the most favourable conditions. The lying-in room should be roomy and well-ventilated, it must not communicate with a water-closet or a bath-room, and any fixed washing-basins in it must have their pipes plugged, and must not be used. If it be necessary for the practitioner to attend a case of midwifery when he has recently been in contact with a case of septic infection, he should, after the most thorough cleansing of his hands, put on a pair of thin india-rubber gloves which can be sterilised by soaking in a strong antiseptic solution. After delivery the discharge should be absorbed by some form of antiseptic pads, and each time that they are changed the vulva should be cleansed with some efficient antiseptic lotion, the nurse observing the same precautions as during labour.

(2) *General*.—If the temperature rises during the first week after delivery, and no condition other than some septic mischief can be found to account for the fever, the uterus should be explored with the finger, especially if there be any doubt as to whether the whole of the placenta and membranes have come away. If retained portions of placenta or membranes be found, they must be scraped away with the finger, and the uterine cavity washed out with some quarts of a weak antiseptic solution, such as creoline half a drachm to the pint. If an offensive discharge continues, the intra-uterine douche may be repeated; but this should not be done if the uterus is found to be empty and its mucous membrane smooth. Curettage of the recently pregnant uterus should not be practised; a pair of ovum-forceps may be used with care to separate any piece of placenta so adherent that it cannot be removed by the finger. A careful examination must be made of the vulva and vagina, and any ulcers present swabbed over with a 1 in 500 solution of perchloride of mercury. Vaginal douches, if necessary, may be given two or three times a day.

Further treatment must be directed towards keeping up the patient's strength so as to enable her to combat the poison. For this good nursing is essential. It is of the utmost importance that nutritious fluid food, and as much alcohol as may be necessary, be administered in small quantities at frequent intervals. If vomiting prevent food being given by the mouth, resource must be had to nutrient enemata and suppositories. Pain and sleeplessness may be treated with opium or morphine. Abdominal pain is best relieved by belladonna fomentations, or poultices sprinkled with laudanum, and abdominal distension by turpentine enemata, or the introduction of the rectal tube. The most useful drugs for internal administration are quinine, Warburg's tincture, ammonium carbo-

nate, turpentine and strychnine. The latter should be given in large doses. Inhalation of oxygen may be necessary. The daily transfusion of half a pint of 'normal' saline fluid under each breast appears to be of service and does no harm (*see* SALINE SOLUTION, Infusion of). It assists the circulation, and the action of the skin and kidneys, and so no doubt helps to eliminate the poison. If the temperature rise to a dangerous degree, an ice-cap may be applied to the head, or the patient cold-sponged or enveloped in a cold pack. The results obtained from the use of antistreptococcic serum are still doubtful, but in cases of pure streptococcic infection it appears to be beneficial. If it is to produce any result, it must be employed early in the case and persevered with. If localised suppurative peritonitis occur the abscess must be opened where it tends to point, and encysted collections of pus, such as a pyosalpinx or suppurating ovarian cyst, require treatment on ordinary surgical principles. The most abundant supply of fresh air that can be admitted with safety should be secured.

3. *Puerperal Peritonitis*.—This, though a very frequent complication of puerperal fever, at times occurs independently of it, other symptoms than those consequent upon the local inflammatory attack being absent. It may arise from the rupture of a pyosalpinx, or an ovarian cyst, or by the transmission of infection through the Fallopian tubes or the lymphatics of the uterine wall.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances associated with puerperal peritonitis differ from those described in connection with puerperal septicæmia only inasmuch as they are confined to the peritoneal cavity. There will probably be found an abundance of effused serum or sero-pus, and flaky lymph, and intense congestion of the peritoneum; the abdominal viscera will here and there be glued together, and covered with a yellowish exudation which can be stripped off, leaving a raw bleeding surface. In some cases all that is found in the peritoneal cavity is a dirty thin fluid consisting of serum, some blood, and countless micro-organisms. The uterus will probably be found abnormally soft.

SYMPTOMS.—Generally within a week following delivery a well-marked rigor occurs, followed by febrile disturbance. The patient complains of acute pain in the lower part of the abdomen, at first in one particular spot, but soon spreading over a larger area, and often recurring in acute paroxysms. The thighs become flexed on the abdomen to relieve the tension; the belly becomes much swollen, and excessively tender; and there is generally much tympanites, with obstinate constipation. There is an extremely anxious pinched expression of the face, and the pulse is very characteristic, being quick, wiry, and incompressible. Vomiting soon sets in, and is frequent and persistent. If the disease do not give way, the abdomen becomes more swollen and tense, and no pressure upon it can be borne. Everything that is taken is vomited; the pulse becomes more rapid and feeble; the tongue is dry and raspy; the patient complains of intense thirst; the constipation gives way to diarrhœa; the skin becomes clammy, and the extremities cold; and the patient dies, usually within three to seven days from the onset of the symptoms. There may, however, even in the worst cases, be no abdominal tenderness or pain, and no fever.

TREATMENT.—Hot fomentations and counter-

irritants, such as turpentine, and in some cases iced flannels, are often of great service in subduing the local inflammation and relieving pain. In the first stage a copious enema of thin gruel with castor-oil, to obtain a free action of the bowels, should be given. Where there is much tympanites, the addition of turpentine may be of benefit in dispelling the flatus. If vomiting prevent nourishment being taken by the mouth, stimulant and nutritive enemata must be given every six to eight hours. For the relief of excessive pain, or where the issue is certainly fatal, morphine may be administered. Strychnine in doses of $\frac{1}{60}$ or $\frac{1}{40}$ of a grain may be given hypodermically every hour for its effect upon the heart and nervous system. The performance of abdominal section with free flushing out of the peritoneal cavity often offers the only possible chance of recovery.

4. Embolism and Thrombosis of the Pulmonary Artery.—**DEFINITION.**—The occurrence of a blood-clot in the right side of the heart or pulmonary arteries, either formed *in situ* or conveyed there from a distance by the blood-current, often giving rise to sudden death after delivery.

ANATOMICAL CHARACTERS.—The condition of the blood in pregnancy and the puerperal state renders it liable to form a coagulum, and this may occur in distant vessels. It is well known that in the later months of pregnancy the amount of fibrin in the blood is very greatly increased. Together with this, a diminution in the volume of the blood from uterine hæmorrhage produces a state of exhaustion, which causes a great predisposition to thrombosis. If, therefore, such having occurred in distant vessels, a portion of coagulum become detached, and be carried away till it reach the pulmonary arteries, embolism is the result, and this is one of the great causes of sudden death occurring after parturition. Some writers affirm, however, that pulmonary thrombosis may occur independently of embolism; large, firm, decolourised coagula have been found, on *post-mortem* examination, occupying the right side of the heart and the larger branches of the pulmonary arteries, which have evidently formed there, all traces of thrombosis elsewhere being absent. It is not certain that in all these cases a sufficiently careful search has been made for the primary thrombus. From a study of twenty-five cases Playfair concluded that if the accident occurred before the nineteenth day of the puerperium the obstruction is most probably due to a primary *thrombosis*; after the nineteenth day to *embolism*.

SYMPTOMS.—These are common both to embolism and pulmonary thrombosis. In the great majority of cases, the patient is suddenly seized with severe dyspnoea; she starts up and gasps for breath; the face in some cases has been described as pale, in others livid. She feels she is dying, and calls out for air, although it is entering the lungs quite freely; the pulse becomes almost imperceptible; and generally death occurs very rapidly. If the patient be examined during the attack it is probable that a murmur will be heard over the site of the pulmonary artery. In some cases in which the clot is not sufficiently large entirely to obstruct the circulation in the lungs, it appears that absorption may ultimately take place, and complete recovery ensue.

TREATMENT.—In almost every case so rapidly fatal is the seizure that there is no time to think of treatment. When, however, the attack is not so

terribly rapid in its termination, every effort must be made to rally the patient, by the administration of stimulants, such as brandy, ether, or ammonia, if at hand. Ether may be given subcutaneously, and the ammonia in large doses, with a view to dissolving the clot. If the patient survive the attack the most perfect rest must be enjoined, so as to prevent the coagulum from becoming dislodged, and to promote its absorption. *See* PULMONARY VESSELS, Diseases of.

PULMONARY DISEASES.—*See* LUNGS, Diseases of.

PULMONARY HYPERTROPHIC OSTEO-ARTHROPATHY.—*See* p. 19.

PULMONARY MURMUR.—This term may be employed in two senses, namely, as signifying, first, the respiratory sound heard over the lung; or, secondly, a bruit heard in connection with the pulmonary artery and its valves. *See* HEART, Functional Diseases of; HEART, VALVES AND ORIFICES OF, Diseases of; PHYSICAL EXAMINATION; and PULMONARY VESSELS, Diseases of.

PULMONARY VALVES AND ORIFICES, Diseases of.—*See* HEART, VALVES AND ORIFICES OF, Diseases of; and PULMONARY VESSELS, Diseases of.

PULMONARY VESSELS, Diseases of.—The vessels of the pulmonary circulation, more especially the veins, enjoy a considerable immunity from disease. Primary affections of these vessels are of most exceptional occurrence, and the causes leading to their being secondarily involved are not numerous. It is not easy to account for this. The pulmonary arteries much less often present those diseased states which are of frequent occurrence in the arteries of the systemic circulation, and are not even as commonly affected as the systemic veins, with which they somewhat more closely agree in point of structure, and in the kind of blood carried by them. The portal vein, which is comparable to the pulmonary artery in other respects besides its plan of distribution, would appear to be similarly free. For these reasons affections of the pulmonary vessels are rather of pathological interest than clinical importance; in the majority of cases they are not to be recognised during life, or, if so, are beyond the application of any treatment. The trunk of the artery, and especially the orifice in the right ventricle, is singularly liable to present congenital abnormalities, which are treated of in the article HEART, Malformations of.

The diseases of the pulmonary artery will now be discussed in the following order: (1) Inflammation; (2) Degeneration; (3) Ulceration; (4) Dilatation

and Aneurysm; (5) Stenosis; (6) Rupture; and (7) Embolism and Thrombosis.

1. Inflammation.—Acute arteritis affecting the pulmonary artery is of very rare occurrence, and usually co-exists with acute endocarditis. Previous to birth it seems to be more liable to exist than subsequently, and some of the congenital deformities of the pulmonary artery and its valve are to be attributed to it. After birth it is almost invariably associated with such acute blood-diseases as pyæmia, or with those pyrexial states which are apt to assume a septic character, as scarlet fever. Emboli, especially if of a putrid character, which have become lodged in branches of the vessel, are liable to set up inflammation in the contiguous walls. Chronic arteritis, leading to atheroma, though far less frequent than in the aorta, is not of very rare occurrence, and under very much the same conditions, namely, increased strain of the vessels, associated with obstruction to the pulmonary circulation, and an hypertrophied right ventricle. When the vessels have become much dilated, as from extreme mitral stenosis, the walls thus thinned are liable to undergo changes of a chronic inflammatory character. *See* ARTERIES, Diseases of.

The anatomical characters correspond with the usual characters of arteritis and arterio-sclerosis.

This state is only demonstrable after death; during life it is not recognised, unless the valves be affected, by any known signs or symptoms, and a diagnosis of its existence has not hitherto been attempted. Under such circumstances no plan of treatment can be laid down.

2. Degeneration.—*Fatty degeneration.*—Fatty degeneration of the intima, without any previous inflammation, occurs in the pulmonary as in other arteries.

Amyloid disease has been seen in the muscular coat of branches of the pulmonary artery.

3. Ulceration.—As already said, inflammation of the vessel-walls very rarely extends to ulceration of the inner coat, but owing to the extreme frequency of ulcerative destruction of the lung-tissue, the intra-pulmonary branches of the vessels are constantly involved. Phthisis, abscess, or gangrene of the lungs, may each in their progress invade the vessels, the walls of which, though offering considerable resistance to the destructive process, sooner or later yield, and may cause a fatal hæmorrhage, though very frequently this is prevented by thrombosis and obliterative arteritis.

4. Dilatation and Aneurysm.—**ANATOMICAL CHARACTERS.**—Varying degrees of abnormal distension are not unusual, occurring in both sexes and in all ages beyond childhood, and are estimated as forming $\frac{3}{4}$ per cent. of aneurysms of all kinds. The dilatation may affect the trunk uniformly; and an extreme case has been recorded where the circumference of the vessel attained $6\frac{1}{2}$ inches, the normal average being taken at $3\frac{1}{2}$ inches. Or, limited in extent, the bulging forms a sacculated, or, more rarely, a dissecting aneurysm of the trunk or branches, from the size of a walnut to a pea, or even smaller, these latter being frequently multiple. The conditions which lead to these alterations in the normal calibre of the vessel are—(a) Those causing a diminished resistance of their coats to the blood-pressure, especially if this be increased, which is often the case, by obliteration of some vessels, and consequent rise in tension in the remaining ones; or by general obstruction, such as mitral

stenosis or emphysema would cause. (b) Those changes in the lung-structures which diminish the support of the vessels, and so allow of their yielding. The results of arteritis and atheroma will furnish the first condition, and ulceration and destruction of the pulmonary tissue as in local tuberculosis will provide the latter. The trunk of the artery has been frequently found unduly dilated in anæmia. The walls of true aneurysms may be thicker or thinner than those of the healthy vessel, and it is remarkable that their contents are said to be never laminated coagula, even in the largest, but always fresh clots. *See* HÆMORRHAGE, p. 621.

SYMPTOMS.—When the main trunk of the pulmonary artery is the seat of an aneurysmal tumour, there are the usual signs of pulsation and prominence in variable degrees, most marked to the left of the sternum in the second intercostal space; over the same area a systolic bruit of a superficial quality is to be heard, not conducted above the sternum or clavicles; and a systolic thrill is to be felt. There is also accentuation of the second sound, with the signs of hypertrophy of the right ventricle. Should the tumour be of any considerable size, it will give rise to those conditions which commonly follow an obstruction to the pulmonary circulation—namely, lividity, dyspnoea, cough, and general anasarca, with scanty, high-coloured urine; and symptoms of pulmonary embolism may result from detachment of fragments of clot from the sac. In an exceptional case, pallor of the face was noticed. Pain behind the sternum, and headache, also exist. Since the greater part of the artery is included within the pericardium, it is into that sac that rupture will probably occur. Uniform dilatation of the trunk of the artery may be accompanied by sufficient stretching of the cardiac orifice to cause regurgitation into the ventricle.

The small aneurysms of the intra-pulmonic branches give rise to no known symptoms until hæmoptysis indicates their rupture.

DIAGNOSIS.—An aneurysm of the trunk of the pulmonary artery may have to be distinguished from a similar affection of the aorta, or from a post-sternal tumour to which pulsation has been communicated. The tendency of pulmonary aneurysm to extend to the left side, and the non-conduction of the bruit to the vessels at the root of the neck, with the coincident signs of pulmonary obstruction, are grounds upon which to found a distinction, though the distinction from an aortic aneurysm is not always easy.

PROGNOSIS.—This is of necessity grave, whatever the size of the lesion, and many cases of fatal hæmoptysis are due to rupture of a small-sized sac.

TREATMENT.—How far such treatment as galvano-puncture, the administration of iodide of potassium, &c., as pursued in aneurysm of the systemic vessels, is applicable to similar affections of the pulmonary artery, is unknown. For the treatment of the hæmorrhage to which rupture of the smaller aneurysms gives rise, *see* HÆMORRHAGE, p. 621.

5. Stenosis.—A narrowing of the pulmonary artery may take place at the orifice, in the conus arteriosus, or more rarely in the trunk or main branches. In the former situations it is commonly congenital, the result of endocarditis or myocarditis, which, if developed within the first three months of foetal life, is almost invariably accompanied by some compensating lesion, such as intraventricular

communication ; while if the affection of the heart be subsequent to the third month of development, the circulation is carried on through a patent foramen ovale and ductus arteriosus (*see* HEART, Malformations of). It is conceivable that stenosis of the conus arteriosus may be followed by secondary narrowing and closure of the pulmonary artery, and also that defective development of the lungs may cause a narrowed vessel. The condition is very rarely due to any acquired change in the vessel-walls, although a case is recorded of stenosis of the artery from cartilaginous thickening and calcification of its coats. The calibre of the tube may be diminished by the pressure of tumours, such as an aortic aneurysm or adenoid growths, or by the shrinking of cicatricial tissue in the adjacent lungs, or from arteritis following on direct violence.

When stenosis is developed at a very early period of fetal life, the artery remains exceedingly narrow beyond the obstruction. When it occurs late, the vessel may be of normal capacity, and if insufficiency co-exist with the obstruction, it may even be dilated.

SYMPTOMS.—Whatever be the cause of pulmonary stenosis, there will be a deficient supply of blood to the lungs, producing dyspnoea, and the obstruction to the circulation will give rise to all the signs and symptoms of general venous congestion, although to a less degree than in affections of the tricuspid orifice. Hypertrophy of the right ventricle—as evidenced by increased transverse measurement of the area of cardiac dulness, and a forcible impulse felt at the epigastrium, a basic thrill, a systolic bruit, of maximum intensity over the heart's base, and conducted to the left of the sternum, but not audible along the course of the aorta and great vessels, and a marked accentuation of the second sound—is the most important result of this condition. Cyanosis is not a characteristic, and does not occur unless there be extreme venous congestion, or a communication between the two sides of the heart. The association of constriction of the pulmonary artery, both congenital and acquired, with tubercular phthisis, has now been too frequently observed for it to be regarded as a coincidence only, and their relation as cause and effect is generally admitted.

TREATMENT.—This affection is entirely beyond the reach of remedy.

6. Rupture.—Violent effort and great excitement have been followed by rupture of the pulmonary artery, either of the trunk or main branches, when degenerated. Death is often instantaneous, though it may be delayed even some hours. Aneurysms tend to burst sooner or later ; those of the trunk usually opening into the pericardium, while the intra-pulmonary dilations commonly rupture into cavities in the lung. Ulceration, as said, is of very rare occurrence, but a case is recorded of its existence and extension through all the coats of the vessel, with a suddenly fatal termination. Rupture of the pulmonary veins has been recorded.

7. Embolism and Thrombosis.—The pulmonary artery is especially liable to become plugged, both by substances lodged in it from elsewhere, and by coagula originating in the vessel itself. Its relationship to the venous circulation explains this. Portions of broken-down clots developed in the systemic veins, from whatever cause ; the contents of hydatid and other cysts that have burst into the

venous current ; fragments of cancerous and other new-growths, all of which readily travel onwards towards the heart, pass into the pulmonary artery, in the branches of which they become lodged, according to their size. Once located, the plug will increase in size by the deposition on it of successive layers of fibrin, sometimes to such an extent as to obliterate all traces of the original obstructing substance. Occasionally very large thrombi are detached in the systemic veins, and are arrested in the trunk and main branches of the pulmonary artery. The causes of thrombosis of the vessel are various. The rare occurrence of inflammation or degeneration of the artery renders obstruction of the vessel from primary thrombosis very uncommon ; but the development of clots in the smaller branches, in association with pneumonia, phthisis, gangrene, and other destructive lung-diseases, is frequent. In certain septic states, in severe malarial states, in parturient women, and in conditions of extreme anæmia, especially with diminished heart-power, when the blood is prone to clot in the vessels, the pulmonary artery is a favourite locality for this to occur ; though the not unusual occurrence of this condition in women after delivery is more probably embolic in character. Pressure on the pulmonary artery or its main divisions by aortic aneurysm, enlarged glands, or other mediastinal tumours, has been known to cause the formation of a thrombus in the vessel. Thrombi may commence in the right ventricle or, as would appear, sometimes on the semilunar valves, and extend into the trunk and, for variable distances, into the branches of the vessel. Such obstructions are frequently developed during the last hours of life, when the circulation is enfeebled and slow. *See* EMBOLISM ; HEART, Thrombosis of ; and LUNG, Hæmorrhage into.

SYMPTOMS.—The symptoms will, of course, depend upon the extent and completeness of the obliteration of the pulmonary circulation. If only the smaller branches be occluded, the symptoms may be those of pulmonary infarction, and the very moderate dyspnoea or slight hæmoptysis might be equally attributable to the phthisis or other lung-state which had determined the formation of the thrombi.

In another class of cases, when larger branches are blocked, very marked dyspnoea is developed, with such symptoms as are conveniently grouped under the term 'anginal,' such as pain in the præcordia, a sense of great distress and faintness, palpitation, gasping, lividity, and extreme pallor, with cold sweats, but no loss of mental faculties, though often inability to speak, an almost imperceptible rapid or irregular pulse, and jactitation of the limbs. The onset of such a condition may be gradual or sudden ; in the former case it depends on the slow increase in size of a small thrombus ; in the latter on the sudden lodgment in some large branch of the artery of a solid substance that has entered the venous current. In some cases these symptoms are present to an extreme degree, and death follows in a few minutes ; in fact this lesion constitutes one of the causes of sudden death. The appearances are not those of asphyxia, and it is usual to attribute the very rapidly fatal result to syncope or shock, as it would seem to be connected in some way with an arrest of the nerve-governance of the heart. In that class of cases which do not terminate so quickly, it is usual to find that the symptoms abate somewhat, and may be followed at

a variable interval of hours, days or even months by a second or even several attacks, usually ending fatally. The *post-mortem* examination of such cases shows a thrombus of considerable extent, with indications of its having been formed at different times.

Examination of the chest reveals no diagnostic signs. There is very likely to be a basic systolic murmur conducted along the course of the pulmonary artery; but this is not constant, and the heart-sounds are often muffled and indistinct.

DIAGNOSIS.—This is often very uncertain. The conditions in which thrombosis is usually met with, such as in anæmic or parturient women, are those in which breathlessness, cardiac pain, and discomfort, and even a pulmonary hæmic bruit, are of frequent occurrence. The symptoms, when not of extreme rapidity, are very similar to those caused by stenosis of the pulmonary artery, which in itself is difficult to diagnose; and, lastly, the suddenly fatal cases are almost identical in their manifestations with rupture of the heart or of a thoracic aneurysm, or even angina pectoris. The supervention of the above-detailed symptoms in a case of existing phlebitis, in a woman within twelve or fourteen days after child-birth, renders it highly probable that they are due to a clot in the pulmonary artery.

PROGNOSIS.—This is to be looked upon as of the gravest character, if once symptoms arise which indicate the existence of a clot in the pulmonary vessels. The smallest plugs formed in branches which are being invaded by a progressive destructive change in the lungs, are protective in character, and prevent or diminish an hæmoptysis which erosion of the vessels might produce.

TREATMENT.—In the most rapid cases death takes place before anything can be done; but in the less severe cases two points have to be attended to, namely, absolute rest, and free stimulation by brandy, digitalis, ether, and ammonia, for by such means only can any hope be entertained of preventing an extension of the clot. Sinapisms over the cardiac region often afford relief, but opiates for the sleeplessness which is met with in some of the prolonged cases are very badly borne.

W. H. ALLCHIN.

PULSATION (*pulso*, I beat).—Pulsation is a sensation of beating or throbbing, either objectively appreciated by inspection or palpation, or subjectively felt. It originates in the presence of a pulse or rhythmical rise and fall of blood-pressure, whether normal or abnormal, in connection with the part where it is situated. In most instances this is either the heart or some large blood-vessel; but in other instances the pulsation has a different origin, especially when the phenomenon is abnormal. As instances of *normal* pulsation may be mentioned the cardiac impulse; the arterial pulse generally; the pulsation of the umbilical cord; and the beating of the fontanelles. *Abnormal* pulsation may be preferable (1) to dilatation of a blood-vessel, as in aneurysm; (2) to vascular dilatation and cardiac enlargement, as in aortic incompetence; (3) to vascular dilatation and cardiac excitement, as in exophthalmic goitre; (4) to interference with the passage of blood through a vein, or even regurgitation into it, as in the jugular pulse of tricuspid disease; or (5) to the pressure of a tumour upon a large vessel, conveying the normal pulse unnaturally to the surface of the body, as in tumour of the

pancreas or pylorus. Pulsation may also be present (6) in any part when it is the seat of inflammation, the small vessels being dilated; (7) in aneurysm by anastomosis; (8) in malignant disease of bone, which may closely simulate aneurysm; and (9) very rarely in connection with empyema. See PLEURA, Diseases of.

With respect to the characters of this phenomenon, it is of great practical importance to distinguish *true* expansive or eccentric pulsation from pulsation which is *communicated* only. In the former case the seat of pulsation expands rhythmically in all directions; in the latter case it is moved in one direction only, that is, it rises and falls under the influence of the motion conveyed to it.

The various pathological conditions which give rise to pulsation, and their treatment, are fully discussed under appropriate heads.

J. MITCHELL BRUCE.

PULSE, The.—SYNON.: Fr. *Le Poulx*; Ger.

Der Puls.—A pulse can be felt in any accessible artery, but the most convenient is the lower end of the radial artery where it runs over the radius. If a finger be placed gently on the radial vessels it will be raised with each beat of the heart, owing to the varying resistance of the vessels. It has been found by experiments on animals that a pressure, corresponding to the actual blood-pressure in the vessel as measured by a manometer, gives the greatest excursion. When the pressure is insufficient, the tissues outside the artery do not transmit the beat well, and when the pressure is too great the vessel cannot expand efficiently. The pressure on the vessel flattens it, and what is felt is the return of the artery to a circular shape, as the blood-pressure varies. It is not the distension of the artery by the passage of the blood which constitutes the pulse, but chiefly the variations in the impulsive pressures which are suddenly transmitted along the artery with the varying changes in the pressure in the aorta. These variations are more marked with a low arterial tension than with a high. If three fingers be placed over the line of the artery, the first may be employed to produce varying pressures, the second to note the effect on the vessel beyond, and the third to cut off any regurgitant changes of the pressure in the vessel beyond. The size of the vessel of course varies, but the alteration is intensified by the application of pressure to the vessel.

The pressure which is applied by the first finger and which is required to obliterate the pulsation in the vessel beyond should always be noted. This will be found to vary under different conditions. When the vessel is lax, the size of the vessel will be felt to be large, and a moderate pressure will be generally sufficient; when the vessel is contracted, the size will be felt to be smaller, but a greater pressure will be required to compress the vessel completely, so that no pulsation can be felt beyond.

It used to be assumed that the channel under the fingers, with its varying pressures and sizes, consisted only of the artery, and the presence of the veins was ignored. In 1897 it was pointed out by Hill and Barnard that the varying vessels consist of the artery and the adjacent *venæ comites*, and that the distension of the latter markedly altered the character of the pulse. With venous obstruction, the pressure in the vein may equal that in the artery,

and both finger and sphygmograph are quite incapable of determining how much is due to the vein and how much to the artery. Hence in all discussions of the pulse and the size of the artery, as determined by the finger or by various instruments, we must bear in mind that it is the size and the tension of the combined cord consisting of the vein and artery which we are discussing, and that many of the older discussions which dealt solely with the artery were in consequence not infrequently erroneous in their conclusions.

The movement of the vessel, as perceived by the finger, at first appears to be simple, but when registered by a sphygmograph it will be noticed to be complex, consisting of two or more waves, and it will be convenient to study these characters from the tracings, which are discussed under the article SPHYGMOGRAPH.

These characteristics may be best appreciated by placing three fingers over the radial artery and passing them to and fro. The fingers readily note the size of the pulse-wave, and the thickness and rigidity of the vessel wall, but they are not capable of recognising small variations in the size of the vessel under different conditions.

A gradually increasing pressure is applied by the proximal finger. When the tension is low, the pulsation beyond is readily stopped, but when it is high the beat, which was at first not marked, becomes more striking, and the pressure required to finally obliterate the pulsation beyond will be above that which we learn by experience to be the normal. The middle finger notes when the pulsation ceases, pressure also being applied by the distal finger to cut off the reflux current through the palmar arch, which is sometimes well marked. Observation with instruments shows that when the vessel is small and contracted, the finger under-estimates the amount of the pressure. The finger gives only a rough idea of the pressure, as no method by which the pressure is transmitted through a solid medium, such as the finger, can give reliable results when the thickness of the tissues over the vessels, as found in different individuals, varies.

It will be convenient to consider in succession the following characters of the pulse and of the vessel: (1) Vessel-wall; (2) Size of vessel; (3) Tension of pulse; (4) Rate; (5) Rhythm; (6) Characters of pulse; (7) Amplitude of pulsation.

1. Character of the Vessel-walls.—When the tension in the vessel is inhibited by firm pressure above, a finger rolling the artery gently beneath it feels whether it is thickened, rigid or calcareous. It is also noticed whether it is tortuous, and an opinion can be formed as to the amount of atheroma and degeneration there is present. When the vessel is degenerate and inelastic, it also elongates, hence the circulation tends to make the vessel tortuous, and the curvature travels along the vessel, producing a locomotor pulse.

2. The Size of the Vessels.—Although a finger will appreciate whether an artery is constricted or dilated, it will not detect small differences; nor can it record the size for comparison between one observation and another. The most convenient apparatus for this purpose is the arteriometer, designed by Dr. Oliver. This instrument measures the difference in the diameter of the vessels, when they have only the weight of the button resting on them, and when the compression has been sufficiently increased just to obliterate the

pulsation beyond. In using this instrument attention must be paid to several details in order to obtain accuracy, and considerable practice is required before reliable results can be obtained. The muscles of the arm must all be relaxed, the wrist, which, at the time of observation, should be at the same level as the heart, must be over-extended at a constant angle, and the radial side somewhat raised. The arteriometer, held between the finger and thumb, must be placed with the central button accurately on the vessel, care being taken that the two outer legs are well supported on the bone and tendons, and that the instrument is held quite vertically. Increasing pressure is then applied until no pulsation can be detected beyond. In this way the size of the compressible vessels may be measured, and although in health the size of the radial veins is negligible when the wrist is over-extended, this is not the case in asphyxia, when they may cause an increase of as much as .6 mm. Probably this will account for part of the increase in calibre, which is observed in recumbency, in some abnormal conditions when gravity becomes a potent factor. In a vigorous individual the splanchnic vaso-motor tone comes into play, to counteract the effects of gravity, and to prevent the blood from gravitating into the abdominal veins in excess, in the erect posture. Hence this tone is best studied by observing the effects of change of posture, and the calibre should be taken, both in the recumbent and in the sitting or erect posture. In health in the recumbent position, the calibres vary from 1.5 to 1.7 mm., and in the erect from 2.0 to 2.3. In many normal conditions the calibre varies directly with the mean arterial pressure, but this is not universally so.

In healthy, vigorous individuals the calibre is generally found to be at its minimum in the recumbent position. It is at a maximum, during the digestion of a full meal, after muscular effort, and as the result of fatigue, or when an individual is 'out of health.'

A. Conditions under which the radial calibre is diminished in size.—(1) Recumbent position. (2) Congenitally small artery; the mean pressure will then be normal, and the usual changes in calibre with alterations in posture will take place. (3) Exposure to great cold or to a temperature above 100° F. (4) Massage in the form of *pétrissage*. (5) Low arterial pressure. (6) Arterial constriction; in this condition the arterial pressure is raised, and the usual alterations due to changes of posture do not take place.

B. Conditions under which the radial calibre is increased in size.—(1) By exercise, digestion, exposure to a temperature between 97° and 103° F., and by massage in the form of *tapotement* or *effleurage*. (2) Congenitally large vessel; when the pressure and the variations with change of posture are normal. (3) Increased arterial pressure. (4) Dilated atheromatous vessels.

C. Conditions under which the calibre ceases to vary with posture.—(1) Excessive blood-pressure. (2) Marked constriction of the vessels, as with megrim, hysteria, &c. (3) Arterial degeneration, as in syphilis, chronic goutiness, Bright's disease, and arterio-fibrosis.

D. Conditions in which the calibre is less in the erect than in the horizontal posture.—(1) Neurasthenia and exhaustion, from whatever cause the latter may arise.

3. **Tension.**—The tension of the wall varies directly with the blood-pressure, but also inversely as the diameter of the vessel. The pressure can be roughly estimated by the finger, but the tendency is to under-estimate the pressure when the artery is contracted. To detect the slight variations, and to record the amount it is necessary to use some instrument. Although there are several of these, they have not come into daily use in Great Britain, hence they require some practice before reliable results can be obtained with them.

Hill and Barnard have devised two instruments depending upon the principle that if a tampon be applied to a vessel with varying pressure, and be arranged so as to transmit, by means of fluid or air, its pulsations to a recording scale, the greatest pulsation will be obtained when the pressure in the tampon is equal to the mean pressure in the vessel. This has been determined by experiment, and it has been found that the same pressure is recorded in all the superficial vessels whether carotid, radial or femoral, provided (1) that the pad over the vessel is not solid, (2) that the pressure be estimated at that which gives the largest pulsations, and not at that which obliterates the pulsation beyond. In one form an indiarubber bag is strapped round the arm, and the pressure in the bag, which communicates with a manometer, is gradually increased and diminished until the maximum pulsation has been obtained; the corresponding figure gives the arterial pressure. The process is too uncomfortable to be applied to clinical work at all generally. In the other, a small manometer containing fluid is applied over the vessel to be observed, and the pressure which gives the maximum pulsation is the one required.

A similar instrument, the *Hæmodynamometer*, devised by Oliver, fitted with a fluid pad, is the most convenient and gives reliable results.

Some practice is required to determine at which pressure the pulsation has the largest amplitude, and since this is more obvious when the amplitude is small, it is often useful to insert a small piece of wash-leather between the artery and the recorder. The maximal pulsation-pressure, which may be called the *mean pressure*, is about two-thirds of that required to stop the circulation, which may be called the *maximum pressure*.

The same instrument can be used to determine the venous pressure. The pad is applied firmly at the distal part of a superficial vein after it has been emptied by pressure, and as the pressure is relaxed, it is noted at what figure the blood returns into the vein. The effect of gravity on the venous pressure according to the position of the vessel, above or below the heart, can be accurately measured; the pressure in a vein on the foot may be 15 mm. Hg. in the recumbent and 135 mm. in the erect position. The venous pressure varies in proportion more with posture than does the arterial: in the recumbent it may be 10 to 15 mm. and as much as 20 to 30 in the erect; the hand in both cases being kept at the heart-level.

It is immaterial whether the pad rests exactly on the vessel, or whether it be separated by a layer of wash-leather, provided the pulsation is still visible. The pressure, whether arterial or venous, is largely affected by gravity, and 1·9 mm. Hg. must be allowed for every inch that the vessel is above or below the position of the heart. When this allowance is made, it is found that the arterial pressure

over the body is uniform. The mean arterial pressure is in the recumbent position 90 to 100 mm. Hg., and in the erect (the wrist being kept at the level of the ensiform cartilage) 100 to 120. Fatigue or loss of vaso-motor tone may abolish this difference, and in conditions of exhaustion the pressure may be the higher in the recumbent position. Exercise, emotion and digestion all raise the pressure temporarily. The vaso-motor tone may also be measured by noting what effect a weight of 28 lbs. distributed over the abdomen has on the radial pressure in the recumbent position. In a feeble person it may amount to 15 to 30 mm. of Hg., while after exercise or in the vigorous it may be nil. One, if not the most essential change in connection with puberty, is the marked increase in arterial pressure which takes place.

Conditions under which high tension occurs.

The pulse tension will be found to vary considerably in healthy individuals; but every alteration which takes place is of importance to the individual. Increase in the volume of the blood due to ingestion of fluid, and frequent, powerful action of the heart due to exercise or exertion, are only temporary causes of increased blood-pressure. Arterial contraction is the principal cause. This may result from exposure to cold, or may occur in hysteria and megrim. An anginal attack is not infrequently started by chilling of the skin, and the same cause may produce, during swimming, 'fatal cramp'—really an arterial spasm which the heart is unable to overcome. With increasing years, as an hereditary condition, with renal disease, gout, lead-poisoning, pregnancy, and sometimes with anæmia, and also with emphysema and chronic bronchitis, the tension may be markedly raised. In anæmia a systolic apical bruit with a high-tension pulse is more likely to be due to the anæmia than to valvular disease. Craig has drawn attention to the frequency with which high tension is met with in melancholic patients. The daily consumption of large amounts of either meat or alcohol, sedentary habits and constipation, all tend to induce high tension.

FIG. 1.—Trace of Pulse of High Tension.

Characters of a high-tension pulse.—1. An amount of pressure must be applied, considerably above the normal, before the characters of the pulse can be elicited, when the beat will become more forcible. 2. The pressure required to obliterate the pulsation beyond is above the normal. The pulse is generally prolonged, nor can any diastolic wave be felt, until the heart has dilated and failed.

The vessel may be either large or small; when the latter, the pulse may be barely perceptible, until pressure is applied; and in consequence the mistake is often made of considering it to be feeble. There do not appear to be any characteristic mental or physical qualities associated with either high- or low-tension pulses in conditions of health.

Conditions under which low tension occurs.—This may be due to cardiac failure, to dilatation of the peripheral vessels, or to diminution of the fluid in the peripheral circulation, whether due to a

diminution in the total amount of blood or to the dilatation of the abdominal veins, which are capable of holding all the blood normally distributed throughout all the vessels. A great loss of fluid, whether from hæmorrhage, vomiting, or diarrhœa, will induce low tension. External warmth, fatigue, exercise, insufficient food, debility, pyrexia, and many toxic conditions will produce a low-tension pulse. It also occurs congenitally, and in cases of fatty heart.

FIG. 2.—Trace of Pulse of Low Tension.

A low-tension pulse is sudden and short, it subsides very quickly, and a very moderate pressure will obliterate it. The dicrotic wave is well marked at the onset of an acute fever, the heart's action is vigorous and the volume of the pulse is much larger than in cases of cardiac failure.

Patients with habitually low tension bear purgatives, especially mercury, badly. The prognosis for a patient with low tension in a disease in which the tension is usually high is unfavourable.

4. **Frequency.**—The frequency of the pulse depends on the rate of the heart's contractions. This rate varies with age, position, sex, stature, and a number of physical and psychical influences. In the newly born infant the heart and pulse beat some 130 to 140 times a minute. The rate gradually falls, and after the sixth year it is usually below 100; and a further decrease of 30 beats a minute gradually occurs before the rate of manhood (70 to 75 a minute) is reached. In old age the pulse-rate often rises again slightly.

In the erect posture the pulse-rate is about ten per minute more in the male, and seven in the female, than when sitting; and when recumbent it is about five less. The pulse-rate of a girl of seven averages about ten beats per minute more than that of a boy of the same age. As regards stature, we may say briefly that the rate is decreased in the tall, being three or four beats less in a man six feet high than in one five feet six. Movement and exertion of all kinds quicken the pulse and emotion or excitement may produce a very high rate in a neurotic person. When examining candidates for life-insurance, as well as when visiting patients, this must be taken into account. A large meal increases the fullness and frequency of the pulse, as does the use of stimulants in health; on the other hand, in acute disease, they often reduce the pulse-rate, which would be good evidence of their beneficial action. The pulse is less frequent in the night and during sleep; it rises in frequency during the early hours of the day, and falls to a minimum about midnight.

Increased Frequency.—In almost all forms of illness the pulse-rate is increased; while in debility and anæmia the rate is also very unstable, being suddenly increased by slight exertion or emotion, the tension generally being below the normal. Pyrexia produces a rapid pulse with dilatation of the peripheral vessels. At the onset of an attack the heart's action is forcible and the vessel lax; hence, not only is the rate increased, but the pulse will be large, sudden, short and dicrotic, the rate

tending to increase with the temperature. As the fever continues the heart's action becomes more feeble, and the pulse smaller, so that its size and rate become of great importance in estimating the condition of the heart. All the conditions for the production of dicrotism are present, and it is in fever therefore that it is most commonly met with. In scarlet fever the pulse is especially rapid, and may run up to 120 or 130 in an adult, and in a child to 150 or 200, without indicating excessive danger. In pneumonia, a pulse of 120 or more in a man at the onset should always give rise to grave anxiety, as it may be the only indication at that time of the seriousness of an attack which may subsequently end fatally. In women or children, on the other hand, such a pulse would, of itself, not give rise to any anxiety, as their circulation is much more unstable. It requires a considerable disturbance to upset the stability of the pulse-rate in a vigorous man, and its occurrence is therefore of greater significance. In phthisis, the presence of a rapid pulse, when the amount of mischief is not great, is of evil omen, as it shows that the patient is very susceptible to the tubercular poison. In all forms of valvular disease of the heart, with the exception of aortic stenosis, the rate is increased. In septicæmia and peritonitis the pulse-rate is of greater importance in prognosis than is the temperature, and is a measure of the effect of the poison on the nervous system. The heart's action is excessively rapid in digitalis-poisoning, and in the later stages of meningitis.

Persistent frequency results from overstraining the heart with exertion, and is not infrequently met with in young soldiers, in those who have over-exerted themselves at athletics, and in middle-aged persons suffering from atheromatous arteries, although the efforts which have set up a dilatation of either one or other cardiac ventricle would have been harmless to younger men.

Rapid action is also a cardinal feature in Graves' disease, and sometimes may be the first symptom. The rate may remain at 120 or much more for weeks at a time in spite of treatment, and is rarely under 100.

Cases of tachycardia or rapid action of the heart as the only abnormal symptom have been recorded by Bristowe and others; the rapidity persists in spite of treatment. These cases generally die within a few years, and often no lesion can be found.

Diminished Frequency.—In comparatively few diseases is the pulse-rate reduced. The most important is that due to high tension in the aorta, with which chronic renal disease and atheromatous arteries are not infrequently associated. It is met with in fatty degeneration of the heart; in aortic stenosis, when the rate may fall to 20 or less; in jaundice; with any lesion that produces intracranial pressure after an epileptic fit; in convalescence from pneumonia or typhoid fever. At the onset of typhoid fever the rate is slow compared with the temperature. See BRADYCARDIA.

5. **Rhythm.**—This depends upon that of the heart; the deviations from regularity may be of two kinds, *Intermittence* and *Irregularity*.

Intermittence is the term applied when there is a beat entirely missing from time to time, while the pulse in between is perfectly regular. The intermission may occur regularly every fourth, fifth, or tenth beat, or it may occur irregularly. Here the auricle contracts on receiving its stimulus, but fails to induce

ventricular contraction, or if it does, the contraction is too feeble to be detectable at the pulse, and intermission results. Hence it generally happens that the next contraction of the left ventricle is more forcible than the previous one. Intermissions may be met with in the young in connection with the excessive use of tobacco; but are more common in later life, when they also occur with dyspepsia, gout, and sometimes from excitement or fatigue, and more rarely from degeneration of the heart-muscle. Effort, such as briskly walking across a room, will increase the intermissions in cases of organic disease, but will cause them to disappear when they are only functional. Intermission disappears usually with an attack of pyrexia.

Irregularity.—In this case the beats are irregular, not only in time but also in force, and the condition is more serious than the preceding. Still, very marked irregularity frequently associated with palpitation may be induced by the use of tobacco or tea, or by flatulence, often producing the greatest distress to the patient; while an organic irregularity may occur without such conscious distress. Irregularity may occur in the healthy on first waking, and also during convalescence from acute diseases. Irregularity is a frequent result of degenerating heart-muscle, and may occur in the last stages of a systole, following various lesions. Most observers consider that irregularity is much more characteristic of mitral stenosis than of regurgitation, probably because the stress in this case falls particularly on the auricle, which more readily fails. Broadbent, however, considers that the reverse is true. When the pulse-rate is irregular it would appear that the failure to contract lies with the auricle.

Sometimes a tracing will show a feeble pulsation when the finger only detects an intermission. The irregularities in these cases are increased by exercise. Inequality in the size of the pulsations often depends on violent expiratory efforts, affecting chiefly the veins. The curve-basis or respiratory line in a sphygmogram falls with deep inspiration as the blood is sucked into the right auricle, while it rises with forced expiration. These variations are most marked with a low-tension pulse, and with high tension are hardly apparent. With forced dyspnoea the curve-basis is undulatory. The pulsus paradoxus is an exaggerated form of this pulse, and is noticeable especially with indurative mediastinopericarditis. The increase in the size of the pulse to be noted with violent expiration is due to the increase in the size of the vein, not in that of the artery, as was formerly supposed.

6. Character of Pulse.—Besides the qualities to which attention has already been drawn, the character of the pulse must be noted. The wave may strike the finger suddenly or lift it deliberately. A sudden or *quick* pulse is produced when the heart empties suddenly into a not over-tense aorta, as in aortic incompetence, with exercise, or at the onset of an acute pyrexial attack. A gradual rise or a *slow* pulse occurs in the opposite conditions, such as rigid vessels, aneurysm, aortic stenosis. The pulse may be felt to last for an appreciable time, forming a *long* pulse, as with high tension; or it may pass rapidly, forming a *short* pulse, as with cardiac failure. The fall may be sudden, as with aortic incompetence; or gradual, as in the early stages of chronic Bright's disease.

A pulse is dicrotic when a second pulsation is felt in the latter part of the beat; this is produced by the momentum of the blood-column as it rebounds on the closed aortic valves, and therefore is best marked when the tension is low. To feel it, only light pressure must be made with the finger.

7. Amplitude of Pulsation.—The amplitude of a pulse is shown in a tracing by the size of the line of ascent and of the tidal wave; these depend on both the amount of blood expelled at each contraction from the heart and also on the state of fulness of the arteries. When the arteries are contracted the pulse is small, hard, and wiry; when the coats are relaxed, it is large and soft. A large pulse is best developed by a vigorously acting heart and a relaxed condition of the arteries, such as obtains at the commencement of an acute specific fever. A flickering pulse is indicative of feeble and unequal ventricular contractions, and the undulatory character noticed in some weak pulses is due to the influence of the respiratory movements on the venous tension. The quality of suddenness, due to the rapid emptying of the left ventricle, gives in a sphygmogram a nearly vertical line of ascent; while the gradual pulse, produced when the ventricle empties slowly, as with aortic stenosis or with a thoracic aneurysm, has an oblique upstroke. The greatest amplitude is met with in cases of aortic incompetence with an enlarged left ventricle, when the pulsation of the vessels in the neck at once catches the eye. The pulse may be impalpable either on account of the feeble condition of the circulation, occlusion of the vessel by a thrombus, an aneurysm, external pressure on the artery, or an abnormal position of the vessel. The pulses in the two radial vessels may be unequal with a thoracic aneurysm; also, one may be retarded and its characteristics but feebly marked. The sudden splashing character of the pulse of aortic regurgitation is greatly intensified when the arm is raised, as the increased pressure in the aorta causes an increased regurgitation, while the same position diminishes the size of the pulse in mitral incompetence.

Gaertner has invented a *tonometer* which is much used in Germany. A finger-tip is rendered anæmic and the middle of the finger is surrounded by an indiarubber bag containing air, which is in connection with a manometer. The pressure is reduced until the blood suddenly rushes back into the capillaries, when the pressure is read off. The instrument is conveniently portable, and an observation does not take more than a couple of minutes. Haig has noted that the time that capillaries take to refill after the skin has been rendered anæmic varies from a normal of about two to about six seconds, when there is contraction of the arterioles. The time can with practice be determined sufficiently accurately with a metronome beating half-seconds.

Capillary Pulsation is most marked in cases of aortic incompetence, and can be brought out by drawing a nail over the skin and thus producing a hyperæmic area which pulsates: or by a microscopic cover-glass pressed on the mucous membrane of the lower lip. It is often present after a hot bath in health, or when the superficial vessels are well dilated from any cause.

Venous Pulsation.—This is often noticeable in the veins of the neck. Normally it is *predicrotic* in rhythm, and the veins do not fill up from below. In tricuspid incompetence, however, with a

vigorously acting right ventricle there will be a *systolic* venous pulsation in the veins of the neck filling up from below, and often also in the liver.

The following arrangement shows in a small compass the principal varieties of pulse met with in practice, apart from the quality of regularity.

A. Varieties of Hard or High-Tension Pulse—*Pulsus durus*.

1. The *hard, frequent, sudden, and small pulse* of peritonitis, enteritis, and pericarditis:—

Pulsus durus, frequens, celer et parvus, fig. 3.

FIG. 3.

2. The *hard, slow, gradual, and large pulse* of contracted kidney:—

Pulsus durus, rarus, tardus et magnus, fig. 4.

FIG. 4.

3. The *hard, large, often gradual pulse* of cardiac hypertrophy and degeneration of blood-vessels:—

Pulsus durus, magnus et tardus, fig. 5.

FIG. 5.

4. The *hard, sudden (jerky), large, and vibratory pulse* of aortic insufficiency, with a strong ventricle:—

Pulsus durus, celer, magnus et vibrans, fig. 6.

FIG. 6.

B. Varieties of Soft or Low-Tension Pulse—*Pulsus mollis*.

1. The *soft, frequent pulse* of pyrexia; dicrotic, fully dicrotic, and hyperdicrotic pulses:—

Pulsus mollis et frequens, fig. 7.

FIG. 7.

2. The *soft, frequent, and large pulse* of rheumatic fever and at the onset of a specific fever:—

Pulsus mollis, frequens et magnus, fig. 8.

FIG. 8.

3. The *soft, small, frequent, and sudden pulse* of debility:—

Pulsus mollis, frequens, parvus et celer, fig. 9.

FIG. 9.

4. The *soft, frequent, and small (running) pulse* of collapse and cardiac failure:—

Pulsus mollis, frequens et parvus, fig. 10.

PUNCTURE.—See ACUPUNCTURE and LUMBAR PUNCTURE.

PUPIL.—The pupil is the aperture through which light is transmitted to the back of the eye. It is situated slightly to the nasal side of the middle line and in health is round. It is not of any fixed or definite size even in the individual, and varies with the conditions to be presently attended to. As a rule the pupils in the two eyes are equal. They are occasionally unequal, however, even in a healthy individual, although inequality is regarded by some as an indication of a neurotic tendency. Contraction of the pupil results from the contraction of the *sphincter pupillæ* muscle; dilatation depends upon the action of the *dilatator pupillæ*, but there is probably also some natural resiliency in the iris itself which accounts for some degree of dilatation.

Contraction of the healthy pupil occurs as a result of exposure to light and also during convergence. Contraction to light is a reflex action. The afferent fibres of the reflex arc run in the optic nerve. There is considerable difference of opinion as to their actual path. It is probable that they partially decussate at the optic chiasma, from thence along the optic tract, go to the corpora quadrigemina, and thence to the part of the third-nerve nucleus which subserves contraction of the pupil. The efferent fibres pass down in the third nerve, to the ciliary ganglion by its short root, and thence pass to the pupil by the short ciliary nerves. There is contraction not only in the illuminated eye but also in the other—consensual contraction. This is probably the result of the decussation of the afferent fibres, and there is probably also a direct connection between the two nuclei. The pupil also contracts during convergence. This is, no doubt, the chief

cause at least of the contraction that occurs during accommodation for near vision, and there is probably a common centre for convergence, accommodation and pupil-contraction.

Dilatation of the pupil is probably the result in large measure of stimulation of the cervical sympathetic. This causes inhibition of the sphincter pupillæ. The latest researches have also shown the existence of a *dilatator pupillæ*. There is probably also some inherent dilating power in the iris itself, for if, when there is complete paralysis of the third nerve, atropine be instilled into the eye, further dilatation will take place. In the lower cervical and upper dorsal part of the spinal cord is the cilio-spinal centre to which fibres pass back from the anterior part of the floor of the aqueduct of Sylvius. The fibres emerge in the first two dorsal nerves, pass in the *rami communicantes* to the cervical sympathetic, thence to the cavernous plexus, the ophthalmic division of the fifth nerve, and along the nasal branch to the long ciliary nerves and thence to the iris. Any sensory stimulus, e.g. prick with a pin, pinching of the skin, &c., will also cause dilatation of the pupil. Emotional states, e.g. fear, produce a similar effect. The condition of hippus is one in which there is rapidly alternating dilatation and contraction of the pupil. It indicates an extremely sensitive, perhaps over-sensitive, state of the contracting and dilating mechanism, and is said to be especially well marked in association with epilepsy. It also occurs in nervous individuals, apart from any structural disease of the nervous system.

The size of the pupil varies in accordance with the degree of light to which it is exposed, the accommodative effect of the eyes, and probably also with mental and emotional states. Unusual degrees of contraction (myosis) and dilatation (mydriasis), and departure from normal reaction to light and during convergence and accommodation, occur as the results of disease. *Myosis* may occur as the result of irritation of the nervous mechanism for contraction, or it may result from paralysis of the mechanism on which dilatation depends. The myosis resulting from irritation may be still further increased by exposure to bright light; mydriatics will overcome it. Paralytic myosis is found most frequently as a result of disease in the cervical region involving the sympathetic path for dilatation of the pupil. The contraction of the pupil may be very great, but its reactions remain. Mydriatics will only partially dilate it. It is only from disease of higher structures that the pupil becomes quite inactive to light as well as contracted, but it may still react during convergence—a condition to be presently alluded to as the Argyll-Robertson pupil. Local conditions should also be remembered as favourable causes of myosis, e.g. excessive vascularity of the iris as in iritis, or when a foreign body is present on the cornea.

Mydriasis or dilatation of the pupil may be *irritative*—the result of irritation of the sympathetic, e.g. from disease in the neck or elsewhere in its path, or as a result of blood-states, which probably act as sympathetic irritants. Anæmia or chlorosis may cause mydriasis by diminishing the vascularity of the iris. Paralytic mydriasis is the result of interference with the pupil-contracting centre or with the path leading to that centre. Thus, disease of the third-nerve nucleus may cause it; so may disease of the nerve itself or of its branches, as in the case of intra-ocular growths.

A very important modification of the pupil as the result of disease is that already alluded to as the *Argyll-Robertson pupil*. In this condition there is often myosis, but this is not invariable. The essential condition is that the pupil while still reacting well during convergence does not react on exposure to light. The pupils also are frequently unequal. Sometimes they are irregular in shape, e.g. oval instead of round. The condition is usually present in both eyes. Rarely it is a unioocular phenomenon, and the unaffected pupil reacts normally. It is usually associated with tabes dorsalis; frequently also it is found in general paralysis of the insane and exceptionally in other central and spinal diseases. It may be present as an isolated phenomenon. It is usually significant of the presence of degenerative disease, or at least of a degenerative tendency in the nervous system. Its frequent presence with conditions regarded as syphilitic or parasymphilitic, and its occasional presence as an isolated phenomenon in patients with a syphilitic history, make it probable that this disease has a close causal connection with it.

Another modification of the ordinary condition occurs after diphtheria. It is almost the converse of the Argyll-Robertson pupil, the reaction to light being present while there is paralysis of accommodation and consequent inability to read, or see clearly at a near distance. Rarely this is an isolated phenomenon. More frequently it is associated with other evidence of post-diphtheritic affection, such as weakness of oculo-motor muscles, weakness of limbs, loss of knee-jerk, nasal voice and affection of the palate. The reaction to light may be absent if the efferent limb of the light-reflex arc is interfered with through affection of the third nerve.

Inequality of pupils may be present in healthy people and is without grave significance. It may be present with the Argyll-Robertson phenomenon. It may also be the result of some irritation of the cervical sympathetic, e.g. from glandular enlargement, &c., and may thus be associated with an increase in the palpebral aperture. If the cervical sympathetic, however, is more profoundly affected, a paralytic condition may be established. This would be indicated by a smaller pupil on the affected side and the presence of a slight degree of ptosis. Inequality or irregularity of pupils may also be the result of anterior or posterior synechie, of operations on the iris, or of developmental defects such as coloboma.

JOHN TWEEDY. JAMES TAYLOR.

PURGATIVES.—SYNON.: Fr. *Médicaments Purgatifs*; Ger. *Abführungsmittel*.

DEFINITION.—Substances which cause intestinal evacuations.

ENUMERATION.—Purgatives are divided into several classes, namely, *drastic, simple, saline, hydragogue, cholagogue, and laxative*. Under the *drastic* purgatives may be classed Colocynth, Croton oil, Gamboge, Jalap, Resin of Podophyllum, Scammony, and Elaterin. Among the *simple* purgatives are Aloes, Castor oil, the juice of various species of Rhamnus (e.g. Buckthorn, Cascara sagrada, and Frangula), Rhubarb and Senna. Under the head *saline* we have neutral salts, especially the Sulphates of Magnesium, Potassium, and Sodium; Citrate and Tartrate of Potassium; Bitartrate of Potassium, Tartarated Soda, and Phosphate of Sodium. *Hydragogues* include Bi-

tartrate of Potassium, Elaterin, and Gamboge. *Cholagogues* comprise Aloes; Mercurial preparations such as Calomel, Blue pill, and Grey powder; Resin of Podophyllum, Iridin, Euonymin, and other substances of the same class. The *laxatives* are small doses of simple purgatives, such as Carbonate of Magnesium, Magnesia, Olive oil and Sulphur, as well as such vegetable substances as contain salines and sugar in considerable proportions, namely, Cassia, Figs, Honey, Manna, Prunes, Tamarinds, and Treacle.

ACTION.—The increased intestinal evacuation produced by purgatives is partly due to acceleration of the peristaltic movements of the intestine, so that the intestinal contents are hurried along more quickly, and less time is allowed for their absorption. Many authorities, especially in Germany, have held this to be the only way in which purgatives act; but there is no doubt that many of them also produce increased secretion from the intestinal glands. The different classes of purgatives affect the intestinal movements and intestinal secretion in different degrees. *Laxatives* and *simple purgatives* act chiefly, if not entirely, by increasing the peristaltic action. Some of the *drastic purgatives* act in both ways; while the *hydragogue cathartics*, as well as the *salines*, especially increase the intestinal secretion. In the case of some of the salines, as acid tartrate of potassium, the secretion is greatly increased, while the peristaltic movement is so little affected that the secretion may lie so long in the intestine as to be again reabsorbed, and the drug therefore fails to produce purgation at all. For this reason it is usual to combine such salines with simple purgatives, which will accelerate the peristalsis, as acid tartrate of potassium with ialap, and sulphate of magnesium with senna.

Besides their direct action upon the bowels, purgatives exert an indirect effect upon the circulation, weakening it, and lowering the pressure of blood within the vessels.

Cholagogue purgatives are those which have a special power to remove bile from the body. They may do this either by stimulating the secretion of the liver, or by quickening the expulsion of bile from the gall-bladder and ducts, so that more bile is poured into the intestine at a time when this is in active movement. The bile is therefore hurried down the intestinal tube, and re-absorption is thus prevented. This appears to be the mode of action of such purgatives as euonymin and iridin. Such mercurial preparations as blue pill and calomel appear to act in a somewhat different way. Experiments, contrary to expectation, have shown that they do not increase the secretion of bile, and yet they are among the most efficient cholagogue purgatives which we possess. Their cholagogue action is probably due to their exerting a special stimulating action upon the duodenum, quickening its peristaltic movements, and thus hurrying down the bile, and preventing its re-absorption. Their beneficial action as cholagogues is greatly increased by the subsequent administration of a saline purgative, which will tend to sweep the bile out of the lower part of the small and the large intestine, and prevent re-absorption from these.

USES.—Purgatives are used, firstly, to remove fecal matters from the intestinal tube. They thus not only prevent the accumulation of such matters, but remove the irritation which their presence produces, and which may evidence itself in disturb-

ances of other organs, for example, headache and malaise. These disagreeable symptoms produced by constipation appear to be partly due to the irritation of the intestinal nerves, producing reflex disturbance of the circulation; but it is probable also that they may be caused in part by the toxic action of poisonous gases, liquids, or solids generated in the intestine by imperfect digestion or decomposition of the food. For such purposes as this we may employ, as we find them necessary, laxatives or simple purgatives. The second use of purgatives is to remove from the body an excess of certain secretions such as bile, and substances which may be contained in them, such as metallic or organic poisons which are excreted in the bile or intestinal mucus. The third use is to remove liquid from the body in cases of dropsy, due either to cardiac or to renal disease. For such purposes we use hydragogue cathartics. The fourth use is to lower the temperature in fever, and for this we chiefly use salines. The *modus operandi* here is not yet well understood. The fifth use of purgatives is to lower the blood-pressure, and thus to prevent the rupture of a blood-vessel, and consequent apoplexy; or to prevent further extravasation in a case where the vessel has already burst, as in hæmorrhage from the lungs.

T. LAUDER BRUNTON.

PURPURA.—Fr. *Purpura*; Ger. *Blutfleckenkrankheit*.—**DEFINITION.**—Purpura is characterised by the appearance of spontaneous extravasations of blood into the skin, and sometimes also by hæmorrhage from mucous surfaces. In many instances it is merely a symptom of some recognised disorder, but in other cases, though strictly speaking it is here also a symptom, it is described as 'a disease,' inasmuch as the primary conditions which give rise to it are unknown.

Characters of the cutaneous Hæmorrhage.—Petechiæ, which are the common feature in all forms of purpura, are red or purple hæmorrhagic spots which become brown as they disappear. They are rounded or irregular in shape, varying in size from a mere speck (as in flea-bite) to a spot half an inch in diameter. They do not fade on pressure. They commonly appear in crops, and they do not increase in size except by confluence. As a rule they are not raised, but occasionally the centre is elevated into a papule which is often paler in colour than the rest of the spot. Occasionally they are linear in shape (vibices). Bruises (ecchymoses) and wheals may be associated with petechiæ; less commonly there are large extravasations into the subcutaneous tissue (hæmatomata).

(a) *Purpura as a Symptom.*—From a review of the conditions under which symptomatic purpura (excluding hæmophilia) occurs we must conclude that it may be produced, (1) by the presence in the blood of bacteria or their poisonous products, (2) by the presence in the blood of some poison of non-bacterial origin either manufactured in the body or introduced from without, (3) by some alteration in the formed or other constituents of the blood, (4) by vaso-motor influence. Thus four classes may be recognised as infectious, toxic, cachectic and nervous.

1. *Infectious.*—In typhus the rash is always purpuric, and a petechial eruption may occur in nearly all the specific fevers, especially small-pox, diphtheria, measles, scarlet fever, plague, yellow

fever, and cerebro-spinal fever. It is rare in typhoid fever. It is not uncommon in malignant endocarditis, pyæmia and septicæmia, and it has been known to occur in association with syphilis, gonorrhœa, malaria, pneumonia and erysipelas.

2. *Toxic*.—The use of iodide of potassium can produce in certain individuals an attack which closely resembles purpura simplex. Poisoning by phosphorus may be attended by cutaneous hæmorrhage. Other drugs such as chloral hydrate, quinine, arsenic, mercury, salicylic acid, copaiba, ergot, belladonna, antipyrine and opium are credited with the production of petechiæ in rare cases. Snake-poison may produce large extravasations of blood into the skin. A petechial eruption may follow the injection of diphtheria-antitoxin. The petechiæ which often occur in the course of chronic nephritis, cirrhosis of the liver, and malignant jaundice should probably be included under this head.

3. *Cachectic*.—Petechiæ are often seen in leucocythæmia, pernicious anæmia and lymphadenoma, and occasionally in connection with generalised sarcoma. In scurvy and scurvy-rickets they may be associated with ecchymoses and hæmatomata. They occasionally occur, especially on the lower extremities, shortly before death from any chronic disease such as phthisis or carcinoma, and even in extreme old age.

4. *Nervous*.—A petechial eruption occasionally appears in locomotor ataxy and more rarely in myelitis, alcoholic neuritis and hysteria.

(b) *Purpura as a Disease*.—Five forms of the disease may be recognised clinically, viz. simple, Werlhof's, arthritic, Henoch's, and febrile purpura respectively. This classification is provisional. The relationship of the various forms is uncertain, and it may be that the distinctions between them are artificial.

ÆTIOLOGY.—In all its forms purpura is almost confined to children and young adults. Both sexes are equally liable. Neither the family history nor the previous history nor the surroundings of the patient throw any light on its causation. The patient is often well fed and apparently in perfect health at the onset of the illness. Occasionally some gastro-intestinal disturbance may immediately precede a simple purpura, and in the more severe forms of the disease an initial tonsillitis is sometimes noted.

PATHOLOGY.—Though the origin of the disease is unknown, the close analogy with idiosyncratic (toxic) and with the purpura of diphtheria and malignant endocarditis (infectious) leads strongly to the belief that in all its forms it comes under one or other of these two heads. In these two examples it must be believed that a circulating poison or an altered state of the blood induces in capillaries and small vessels a subtle widespread preparatory change in the direction of impaired vitality of their walls, and that in this condition various local factors, such as gravity, an unsupported state of a vessel, and sudden alterations in blood-pressure produce rupture and extravasation of blood. No constant microscopical change in the vessels is known. Such gross changes as endarteritis or hyaline and amyloid degeneration of the vessel wall which have been described may be disregarded. Capillary emboli have been found in purpura arising in generalised sarcoma. Bacterial emboli have been found in connection with

petechiæ in certain specific fevers, but they are not constant and they are found without the occurrence of purpura. 'Febrile' purpura bears a close resemblance to a specific fever. No specific micro-organism, however, is known. Streptococci, staphylococci, and a capsulated bacillus belonging to the colon-group have been frequently found in the blood and tissues. But these observations having been mostly made *post-mortem* are of little value, and the blood taken from a vein during life is generally sterile.

MORBID ANATOMY.—After death no change is found which can throw light on the cause of the disease. Petechiæ are found as thickly distributed inside the body as on the skin. The serous membranes, stomach and intestine are particularly affected. Larger hæmorrhages may be found in the brain or elsewhere. The mesenteric glands are swollen. The spleen is often enlarged. All organs are pale and often fatty. Iron-holding pigment may sometimes be demonstrated in the hepatic lobules, and fatty transformation of the marrow in the heads of long bones has occasionally been found. After death from Henoch's purpura the kidneys may present the appearances of acute tubal nephritis. Though diapedesis may play a part in the production of petechiæ, it has been shown by Unna that the hæmorrhage mainly occurs by rupture of vessels, the site being commonly in the lower part of the cutis.

SYMPTOMS AND COURSE.—1. *Simple Purpura*. The appearance of petechiæ first attracts attention. Few at first, they appear in successive crops, so that in a few days nearly the whole body, face, trunk, and extremities may become thickly sprinkled with red, purple, or rust-coloured spots. Here and there large patches may be formed by coalescence. Ecchymoses are readily produced and sometimes hæmatomata develop, especially about the buttocks.

As in other forms of purpura there may be evidence of slight pain in some joints, and perhaps a little œdema may be detected on the backs of the hands and feet. There may be some epistaxis and less commonly some oozing of blood from the gums, but there is no other hæmorrhage from mucous surfaces. In many cases there is no indication of illness apart from the petechial eruption and a slight degree of anæmia. There is sometimes slight pyrexia during the first few days and a little constitutional disturbance, but recovery occurs in one or two weeks, and there is no tendency to recurrence. It is important, however, to note that the early stage of the more fatal forms of purpura may be as mild as a simple purpura, and that prognosis should consequently be reserved, especially when the temperature is above 100° F. at the onset.

2. *Werlhof's Purpura*.—The onset and early symptoms of this form are generally identical with those of simple purpura, and it may reasonably be considered as a later or more severe stage. After a few days or a week, during which petechiæ appear with little impairment of the general health, the hæmorrhagic tendency becomes aggravated and often uncontrollable. The gums ooze freely, epistaxis may be severe, blood may appear in urine, stools and vomit, and there may be bleeding from the uterus and auditory meatus. Retinal hæmorrhages are not uncommon. Bruises and hæmatomata may arise. The anæmia is profound and the

red cells may fall below 1,000,000 per c.mm. The tongue is slightly if at all furred, and there is little or no pyrexia. Such cases may recover, but death frequently results from exhaustion or from hæmorrhage into or upon the surface of the brain. In rare cases the disease proves fatal (*purpura fulminans*) by extensive hæmorrhage in a few days.

3. *Arthritic Purpura*.—The early stage is here marked by pains in joints, especially in the knees, ankles, elbows, and wrists. The joints are tender, though there may be very little external evidence of inflammation. The condition resembles a subacute rheumatism, but its connection with rheumatism is very doubtful. After a few days petechiæ appear, more thickly on the lower extremities than elsewhere, and often aggregated round an affected joint. Ecchymoses are not uncommon. Slight œdema of hands and feet may often be seen. Pyrexia is moderate and may be absent. There is often very little feeling of illness, and there is no tendency to hæmorrhage from mucous surfaces.

The attack subsides in two or three weeks and need not give rise to anxiety; but there is a strong tendency to recurrence. Further attacks may occur at short intervals even when the patient is at rest under treatment. An attack is very apt to occur when he first leaves his bed, and many months may elapse before he can walk freely.

Certain cases (*purpura urticans*) may provisionally be included under this head, in which to the articular pains and petechiæ already described there is added the presence of wheals and extensive œdema. The face in whole or in part may be greatly swollen and discoloured with petechiæ, wheals, or ecchymoses. The hands and feet in the neighbourhood of any painful joint may be similarly affected. In these cases the onset is usually sharper than in the simple arthritic form, the pyrexia is more severe, a greater degree of illness is reached, and the urine may contain blood or albumen. Tonsillitis has been known to precede such an attack.

4. *Henock's Purpura*.—During the first few days there is little or nothing to distinguish this variety from arthritic purpura. But the main feature soon appears in the form of severe attacks of abdominal colic with vomiting and constipation. The pain is undoubtedly severe and may induce collapse. The vomit soon comes to contain blood, diarrhoea succeeds the constipation, and the stools are black with blood, while epistaxis and oozing of blood from the gums are not uncommon. Occasionally an acute nephritis is added, the urine becoming scanty and containing blood and albumen. Pyrexia is slight and may be absent. The spleen has been found swollen after death, and its enlargement has been detected during life. There is a marked tendency to recurrence of such attacks, but recovery may be expected. Occasionally death occurs with all the symptoms of uræmia, and in one recorded case perforation of the stomach proved fatal on the fourth day of a second attack.

5. *Febrile Purpura*.—In nearly all instances of this form of purpura it is the appearance of petechiæ, perhaps with epistaxis and oozing from the gums, which brings the patient under observation. Sometimes the patient states that he has been out of health for some weeks previously, pallor and a feeling of weakness being the main complaints, but sometimes the onset is as sudden as in any specific fever. In any case the patient is already extremely

pale. The petechiæ appear in crops all over the body, but they are often much less numerous than in simple purpura. Ecchymoses are common. Tender raised bluish-red patches, an inch or more in diameter, may appear suddenly, and these often become surmounted by a bulla containing blood-stained serum. On the breaking of this an ulcer is left which is apt to deepen and spread by progressive necrosis. Petechiæ are always present in the mouth, and they are apt to give rise to small ulcers. Gangrene of gums or of the inner surface of the mouth is a common event, and sometimes progressive sloughing of tonsil, palate or epiglottis occurs. The breath is fetid and the submaxillary glands enlarged. Blood continually oozes from the gums, which are pale and not swollen. Epistaxis may necessitate plugging of the nostrils. Retinal hæmorrhages are often seen, but bleeding from gastro-intestinal or urinary tracts is uncommon. Enlargement of the spleen has occasionally been noted and the joints are sometimes slightly painful. The blood shows a progressive diminution of red cells, which may fall below 500,000 per c.mm. Leucocytosis is slight or absent. During the first few days pyrexia is not always present; but the temperature rapidly rises, and for the greater part of the illness it reaches a maximum of 103° or 104° with a daily range of 2° or 3° . It is doubtful if recovery ever occurs. Sometimes the patient falls into the typhoid state, sometimes he remains clear-headed to the end, presenting a blanched appearance and complaining of nothing but extreme weakness. Death generally occurs in the first, second, or third week after the patient comes under treatment, its immediate cause being cardiac failure.

TREATMENT.—In simple purpura no special treatment is required beyond rest in bed, with the administration of arsenic or iron. In the arthritic form anti-rheumatic treatment is commonly adopted, though the benefit derived is doubtful. More important is the maintenance of prolonged rest in bed in view of the strong tendency to recurrence. In Henock's purpura the pain generally necessitates the use of opium. When hæmorrhage becomes a danger, as in Werlhof's disease, calcium chloride, ergot and ergotin, sulphuric acid, acetate of lead, or turpentine must be tried, but they frequently fail to produce any effect. In the febrile form also these drugs have little or no value, and neither quinine nor anti-streptococcic serum has any influence on the temperature. In fact, in the severe forms of purpura there is little to be done beyond combating the cardiac weakness by stimulants, strychnine, and the inhalation of oxygen.

HERBERT P. HAWKINS.

PURRING TREMOR or THRILL.—SYNON.: Fr. *Frémissement Catairè*; Ger. *Schnurren*.—A physical sign felt by the hand applied over the heart or vessels in certain conditions, resembling the sensation conveyed by the purring of a cat. See PHYSICAL EXAMINATION.

PURTON, in Wiltshire.—Saline waters, containing iodine. See MINERAL WATERS.

PURULENT INFECTION.—Infection from the absorption of pyococci, introduced from without, or formed within the body. See PYÆMIA.

PUS.—See INFLAMMATION; and ABSCESS.

PUSTULE. — **SYNON.** : Fr. *Pustule* ; Ger. *Pustel*.—A small abscess in the skin. Vesicles originally containing serum are also apt to become pustules if infected by pyogenic bacteria.

PUSTULE, MALIGNANT. — **SYNON.** : Anthrax ; Fr. *Charbon* ; Ger. *Milsbrand*.

NOMENCLATURE.—Under this head will be considered the various effects of poisoning by the *Bacillus anthracis*. Various names are employed to designate the different clinical forms, both in man and animals. These names were derived from prominent features of the disease, or from its supposed origin before the real cause was discovered.

In bovine animals, the great swelling of the spleen led to the names of 'Splenic fever,' 'Splenic apoplexy,' *mal de rate*, *Milsbrand*, &c. From the peculiar characters of the external lesion in man, and less frequently in animals, the terms 'malignant pustule,' 'anthrax,' 'contagious carbuncle,' &c., were derived. The especial liability of those engaged in certain occupations, especially those involving exposure to contagion, led to the names of 'wool-sorter's disease,' 'hair-comber's disease,' &c. In like manner, the disease as affecting animals has received special names.

The *Bacillus anthracis* (*bactériidie du charbon* ; *Milsbrandbacillus*), as seen in the blood of an animal affected with the disease, occurs in the form of comparatively large rods, whose thickness is about $1.2\ \mu$ to $1.5\ \mu$, and whose length is generally about the diameter of a red corpuscle, though both shorter and much longer forms are seen (see *Coloured Plate*, p. 123). It is non-motile. The rods may be present in enormous numbers, sometimes appearing to equal the red corpuscles in number. In the blood and in the spleen the rods occur singly, or two or three may be joined end to end, but long chains are not usually found. In the pleural exudate and in similar fluids, as well as in cultivations outside the body, the organism grows into long filaments, which may be shown to be made up of a large number of individual bacilli. The rods have slightly rounded or nearly square extremities, and their protoplasm has a homogeneous or slightly granular appearance, but spores are not usually found in the bacilli within the living body.

Cultivation, &c.—The anthrax-bacillus can readily be cultivated outside the body on all the ordinary media. It grows at ordinary temperatures, but much better about 35°C ., the limits of growth being generally given at 12° – 45°C . On certain media its growth has a characteristic appearance.

In puncture-cultivations in peptone-gelatine the growth appears along the needle-track as a somewhat whitish line from which fine lateral offshoots spread out horizontally in the medium, these also in their turn giving off lines of growth, so as to produce an appearance which has been compared to bunches of fine bristles. The lateral stems are longest near the surface of the gelatine. Later, liquefaction begins at the surface and spreads downwards, so that the characteristic features are lost, and the growth appears as a white flocculent mass at the junction of the fluid and solid portions. In plate-cultivations minute white colonies appear, which, on reaching the surface of the gelatine, cause a little area of liquefaction around them. If these superficial colonies are examined with a low-power lens, the periphery is found to have an appearance like masses of curly locks of hair, the

centre of the colony being denser. The appearance is due to the growth of the organism in wavy bundles of long parallel filaments, which in the centre of the colony are interwoven and massed together. On potatoes the growth is abundant, and appears as a thick cream-like mass, which remains chiefly localised and has little tendency to spread on the surface. The growth on other media presents nothing characteristic. The bacillus also flourishes well in broth and other liquid media.

Growth takes place freely only in the presence of oxygen, and best on a neutral or slightly alkaline medium. The bacilli can be coloured readily by Gram's method, and by the various simple aniline stains.

Anthrax-bacilli in the spore-free condition have comparatively little resisting power to chemical antiseptics, &c. When dried they are generally found to be dead after a few days, and they soon die in fluids in the presence of putrefactive bacteria. They are very rapidly killed by moist heat at 65°C ., and by a 1-per-cent. solution of carbolic acid ; the action of the gastric juice is also rapidly fatal to them, and they are therefore generally killed in their passage through the stomachs of animals. The spores, on the other hand, show a remarkable tenacity of life. They can be kept in the dry state for an almost indefinite period of time, and still be capable of growth when placed in suitable conditions. Dry heat at 140°C . must be applied for several hours in order to kill the spores with certainty, and they may be placed in a 5-per-cent. solution of carbolic acid for a considerable time without being killed. Unlike the bacilli in the spore-free condition, they can pass through the stomach unaltered, and thus reach the intestine in a virulent condition.

Relations to the disease.—When inoculated into susceptible animals (such as mice, rabbits, guinea-pigs, &c.) even in the minutest quantities, this organism causes a rapidly fatal disease. The bacilli generally soon reach the blood, and rapidly multiply, so that they may be present in enormous numbers ; in the spleen also they are very numerous in some animals, and this organ in most animals shows marked enlargement. Death generally takes place in one or two days. The other *post-mortem* changes are chiefly those of a severe septicæmia—congestion and cloudy swelling of organs, and often small hæmorrhages, which are in many cases associated with plugging of the capillaries with small masses of the bacilli. At the seat of inoculation there may be inflammatory œdema, with extravasation of blood ; or there may be little change. In sections of the tissues the bacilli are found in enormous numbers in the capillaries (in comparatively small numbers in the larger vessels) ; in fact, so numerous are they in the capillaries of the kidneys, liver, intestines, peritoneum, and lungs, that in stained specimens these may appear as if injected with a coloured material. Animals may be infected by inhalation either of the bacilli or their spores, the former generally producing a pneumonic condition, whereas the latter may be rapidly absorbed, and produce a general infection with comparatively little local change. Infection by the spores may also take place by the intestinal tract, and this is probably the common mode in the natural disease in sheep and cattle. The modes of infection in the human subject, and the lesions produced, are described below. Certain animals enjoy a natural

immunity against the action of the anthrax-bacillus, for example, adult dogs, white rats, many birds, and frogs; though the susceptibility may be modified by altered conditions of temperature.

In view of the enormous numbers of bacilli which may be present in the blood, it was formerly thought that their effects were produced partly mechanically, and partly by their using up the oxygen of the blood. And though they may act in both of these ways, it is now known that, in common with other pathogenic bacteria, the anthrax-bacilli produce specific toxins. For further details on the toxins and antitoxins, see ANTITOXINS; IMMUNITY; and TOXINS.

Anthrax is of very wide distribution throughout the world, especially affecting cattle, deer, sheep, goats, and allied animals; less frequently horses. But it can be communicated to nearly all animals by inoculation, and even to some birds and amphibians. Of mammals, herbivora are especially susceptible; while carnivora are with difficulty inoculated, except when young. Rodents are highly susceptible, and hence are commonly used for test-inoculations.

Although apparently endemic in certain regions, there can be little doubt that this is due to the great persistence of the contagium by means of its spores, and that the recurrence of outbreaks in cattle is due to the careless disposal of carcasses of animals which have died of the disease.

In man, the disease is usually traceable directly to inoculation from the fresh carcass, or from parts, such as the skin or hair, which have been kept in a dry state. Hence butchers, shepherds, and stockmen, who flay the carcass or bury it, are most commonly its victims from the more direct mode of inoculation; while wool-packers and sorters, horsehair-cleaners, workers in felt-manufactories, furriers, tanners, and the like, are exposed to the less direct form. In rarer instances no such mode of contagion can be traced, and it is probable that in these the poison has been conveyed by flies, or similar agencies. The flesh of the dead animals can rarely be suspected, unless it is eaten raw or very imperfectly cooked. Even then, as we know from experiment, large quantities of the bacillus or its spores may do no harm. Butter and milk are alleged by Heusinger to be possible carriers of the poison. Nor is it improbable that the use of water which has been contaminated by wool-waste, bone-dust, or other substances, may convey contagion to cattle. But none of these modes is proved to be common in man, and the spread of contagion from one human subject to another is extremely rare.

It will, however, be shown that in man the disease may be acquired either by inoculation or by inhalation of the dust containing the spores of the bacillus, perhaps also by swallowing them.

DESCRIPTION.—The form of the disease depends on the mode of entrance, and may be internal or external.

Anthrax in Cattle.—This may be briefly described, as of importance in relation to man. Whereas in some animals there are marked external manifestations, either pustular or of the nature of diffuse phlegmonous swellings, with glandular enlargement, such conditions are rare in cattle. In them there may be not only no external changes, but even few perceptible symptoms. Only for a few hours before death may there be evident languor, loss of appetite, and then stupor. But sometimes

animals may be found dead in the morning which had been apparently well the night before. If, however, they are carefully observed, it is usually found that there is marked rise of temperature, followed by coldness and lividity before death.

On examining the carcass, the blood is often found fluid, and may be dark in colour. Sometimes there are glandular swellings and inflammatory oedema, especially around the pharynx, œsophagus, and stomach. But these are more frequently absent, and there are only scattered hæmorrhages here and there, especially in the lungs and heart-wall, and sometimes in the submucous tissues.

The most constant and characteristic condition is the enormous swelling of the spleen, which is engorged with blood, and readily breaks down on slight handling. This splenic enlargement, be it remembered, is constant only in cattle, and may be entirely absent in other animals, or very slight and irregular.

Microscopical examination shows enormous numbers of anthrax-bacilli in the blood, especially in the spleen, lungs, and, next in frequency, in the capillaries of the glomeruli of the kidneys, and sometimes in the liver. In these organs many of the capillaries may appear to be completely filled at parts with bacilli.

It is very important to bear in mind that this abundance and this distribution of the bacilli are very inconstant in other animals. Only guinea-pigs show a similar condition with any constancy. In other animals the bacilli may be few and scattered, being found especially in the capillaries of the lungs and kidneys; or they may be mainly limited to the lymphatics, including the glands and lymph-cavities. Hence, while all parts of the body of cattle which have died of the disease are actively poisonous, it may be difficult to convey the disease from other animals except by inoculation of the fluid from the more affected parts.

Moreover, the activity of the bacillus is rapidly destroyed by decomposition, so that no results may be produced by inoculation from the dead animal when decomposition has set in, unless spore-formation has occurred. This is also true of the human subject.

Spore-formation is sometimes alleged not to occur during life. It may, however, do so in the kidney, if the bacilli pass into the urinary tubules, and also in serous exudations in the pleura and elsewhere, either before or very speedily after death.

Destruction of the carcasses by fire or by deep burial is essential to prevent infection from them.

Anthrax in Man.—This is divisible into two primary forms, *external* and *internal*, which differ not only in the character of the disease, but in mortality and treatment. The external variety may be further described as *malignant pustule proper*; and *anthrax-oedema*. The internal form may be subdivided, according to the part specially affected, into a *broncho-pulmonary* form, of which 'wool-sorter's disease' is the type; and a *gastro-intestinal* form. There may also be cases which do not come strictly under either of these heads, but more closely resemble the disease in cattle, and have been called *Anthracæmia*.

The external form, malignant pustule, is caused by direct inoculation of the skin, or of a superficial mucous membrane, for instance, that of the lip or the eye. In some cases there is only present an

intense inflammatory œdema, which spreads like erysipelas, and causes enlargement of the corresponding lymphatic glands. It is like the condition to be immediately described, differing only in the absence of the characteristic pustule.

Of these cases of so-called *anthrax-œdema*, it need only be said that some may not be due to the anthrax-bacillus, but to the bacillus of malignant œdema. But there is no reason to doubt that a similar condition may be produced by the anthrax-bacillus.

Malignant Pustule Proper.—The typical form, malignant pustule, can usually be traced to direct inoculation. It commences as a small red swelling or pimple at the point of inoculation. It may give rise to slight irritation, or be attended by burning or itching, but may be absolutely painless. It occurs commonly on the face, neck, hand, or arm, that is, on the parts most exposed to direct inoculation in handling a carcass. The exact period after inoculation at which it appears is variable, owing doubtless to the presence or absence of a small wound: it may be from a few hours to two or three days, possibly longer. Once formed, it rapidly extends, so that in a few hours a large red swelling may be present. There then usually form upon the surface of the swelling one or more vesicles, which, if not ruptured, may reach a considerable size by confluence. By this time a more marked localised swelling has formed; and if the vesicle or bleb ruptures, or is opened, it discharges a watery fluid, either clear or slightly turbid, and often deeply blood-stained. Beneath the vesicle is a dark-red area, which usually dries, producing a dark-brown or black eschar, seated on a much raised, angry red, indurated base. Further vesicles frequently develop around this eschar; they often form a narrow ring surrounding it. The central necrosed area enlarges, and by this time a widespread livid red area and extensive brawny œdema extend from it, sometimes involving the whole arm or face. The corresponding lymphatic glands usually enlarge, often to a great degree, forming a dense mass, owing to the surrounding inflammatory œdema. The central black eschar may enlarge till it reaches one-third to three-quarters of an inch in width; and if the patient survives it may still be distinct, seated on the raised indurated inflamed base, at the end of ten days or more. These characters will be explained in considering the microscopic changes.

In some cases, this typical lesion is indistinct, the brawny red swelling, with some irregular vesicles, being alone observed. When recovery occurs, the swelling subsides more or less rapidly, the eschar separates, and healing takes place rapidly; but the swelling of the glands may last for some time.

Similar carbuncular swellings, more or less typical in character, have also been observed, though rarely, after an internal or general infection, and not as the result of local inoculation.

Microscopic Anatomy of the Malignant Pustule. The descriptions given by various writers of the changes seen with the microscope are somewhat conflicting. The differences are partly accounted for by the different site or stage of the specimens examined. From an examination of numerous specimens at various stages, the changes appear to be fairly constant in their mode of evolution.

In the early stages there may be no indication of

abrasion of the skin, and it is probable that the virus may gain access by the hair-follicles. There is at first infiltration of the corium, with inflammatory exudation, especially in its papillary portion. The epithelium becomes partially separated, and rises in the form of vesicles, as in an ordinary blister, the deeper layers alone remaining attached. Bacilli are found, though scantily, in the serous exudate.

There then ensues a deeper-seated exudation, penetrating to the deeper layers of the skin. This exudation is accompanied by hæmorrhage, and the tissue-elements swell and undergo rapid necrosis. Both the epidermis and the infiltrated superficial layers of the skin necrose and form a coagulated mass, which constitutes the dark central area of the pustule. Around this the processes of vesication and of subjacent hæmorrhagic infiltration go on spreading, both laterally and in depth.

When fully formed, the central part forms a dense, horny-looking, blood-stained mass; beneath and around it are great infiltration, hæmorrhages, and commencing necrosis. Farther out there is œdema and great vascular engorgement, often with but scanty exudation of leucocytes.

In sections stained for bacilli, these are found almost solely in the vesicles and in the lymphatics around the necrosed area. They occur as scanty clusters, and are often most abundant in the more superficial lymphatics. They can be traced for a certain distance from the area of intense inflammation. Their absence in the necrosed area is doubtless explained by the necrosis in which they share. They have occasionally been seen in large numbers among the epithelial cells and in the superficial layers during the early stages of infection.

In more advanced conditions, leucocytic infiltration becomes abundant around the necrosed area.

Some have supposed that the peculiar characters of the pustule are due to the presence of other micro-organisms, which aid in their destruction and in the necrosis of the tissues. It cannot be said that microscopic examination of pustules in the earlier stages lends much support to this view. They point rather to an intense irritant action of the products of the growth of the bacteria on the tissues and vessels, differing markedly from their effects as seen in the blood-vessels of the cow, in which almost no such action is apparent. When the surface has necrosed, other bacteria do no doubt enter, but they do not usually penetrate deeply into the tissues.

The normal limitation to the lymphatics, and their scanty number, the spread mainly in the superficial lymphatics, and the early and intense protective exudation and necrosis which they excite, are all favourable to recovery; and afford strong grounds for the avoidance of any treatment which will break through these natural barriers and produce risk of contamination of the blood.

SYMPTOMS.—The condition of the patient is very varied. Even in cases which prove fatal, there may be few or no general symptoms at first, and he may even continue at work with a large distinct pustule; or there may be only a slight degree of prostration, with a little fever. In some cases recovery ensues without the development of any general symptoms.

More commonly the development of the pustule and of the lymphatic infection are attended by prostration, fever, and some of the symptoms of

general blood-poisoning. The exact character of the symptoms, which will be more fully described under the head of 'Internal Anthrax,' appears to depend on the system which is more specially involved. In some, gastro-intestinal derangement, with severe vomiting, is prominent. In others, delirium, convulsions, and coma occur. In rarer cases, the course resembles that of the bronchial form to be described later.

The temperature is said by some not to be elevated. This may possibly be true in some cases in which there is no general infection, but it is not confirmed by cases investigated by Spear and the writer, or by the numerous medical men under whose care these patients were, and who had carefully watched other cases. The elevation may be slight at first, and in the more advanced condition the surface-temperature may be subnormal; but the rectal temperature is elevated. It may rise to from 101° to 105° F., and in one fatal case it rose to nearly 107° . This point is of considerable importance in diagnosis.

Recovery may take place without special treatment, even where severe constitutional symptoms have supervened. The mortality appears to be about one in four of cases treated without incision. Convalescence may be rapid and complete, or prolonged debility may result.

In some cases, the diffuse cellulitis which spreads from the seat of inoculation may be followed by suppuration, either diffuse phlegmonous infiltration or localised abscess, especially in the glands. The occurrence of diffuse phlegmonous cellulitis appears to be commoner in a class of cases in which the carbuncular swelling is not fully developed, but forms only a small swelling, which usually vesicates. In these cases, also, blebs may form more widely over the inflamed skin, and extensive desquamation of the cuticle may accompany recovery.

TREATMENT.—When any local lesion forms in a person who is known to be exposed to infection, treatment should be at once commenced. If small, the pimple should be incised with a very sharp knife, and suction immediately applied by means of a cupping-glass or artificial leech; the part should then be thoroughly washed with a strong antiseptic, such as solution of biniodide of mercury (1 per cent.) in excess of iodide of potassium, or corrosive sublimate of the same strength, preferably combined with peroxide of hydrogen to prevent coagulation.

If the condition is evidently anthrax, or there has been known inoculation, the more radical method of complete excision and subsequent cauterisation is probably desirable. Of the various methods which may be used, excision is perhaps the best, if it can be done speedily and with little disturbance of the part; but it must be borne in mind that the great risk to the patient's life is in the entrance of the bacilli into the blood-stream, and that the greatest precautions must be taken to avoid this. During the operation the wound should be kept irrigated with antiseptic lotion, preferably biniodide or perchloride of mercury, 1 in 5,000.

Bleeding from the wound may be encouraged by a loose bandage above, in the case of the arm or hand, the object being to prevent the entrance of bacilli into the veins. Arterial bleeding may of course be controlled in the usual way. Antiseptics should be speedily applied. Of these, strong carbolic acid or fuming nitric acid is often recommended; but the caustic action of these so limits

their sphere that probably sublimate or biniodide is to be recommended, except where a caustic action is desired owing to the difficulty of complete excision, for instance, on the face. For a dressing, biniodide solution 1 in 3,000 to 5,000 in 30 per cent. glycerine in water is especially to be recommended; and if applied on several layers of lint, covered with oiled silk, forms a sort of poultice which aids to draw out the lymph. Some recommend carbolic acid or other antiseptics, but these are comparatively ineffective. Oozing from the wound should be encouraged rather than checked.

The diffuse cellulitis may, if necessary, be treated by superficial linear incisions or scarifications, the parts being immediately washed with biniodide lotion, 1 in 2,000. A large poultice of iodide-of-starch paste, to which a solution of biniodide of mercury in a large excess of potassium iodide has been added, in such proportion as to make the poultice of the strength of 1 in 3,000 of biniodide, should then be applied.

The rationale of this treatment lies in the fact that the bacilli lie mainly in the lymphatics of the superficial layers of the corium. The risk of promoting their entrance into the blood must always be borne in mind. Surgical interference is therefore to be deprecated, unless the disinfectant treatment can also be carried out.

Internally, the treatment must consist in supporting the strength, especially by concentrated animal diet, and perhaps by large doses of quinine. Strophanthus should be given if the heart's action becomes feeble.

Internal Anthrax.—This term is more strictly applicable to those cases in which the starting-point is internal, usually by entrance of the virus into the respiratory or alimentary passages. But the conditions which follow general infection from an external lesion are closely analogous.

Of the forms which internal anthrax assumes, the *bronchial* and *gastro-intestinal* are the most typical. Internal inoculation may, no doubt, occur in the mouth, pharynx, &c., as well as in the stomach or intestine. Some have supposed that there may be an entrance into the blood, such as appears to occur in cattle, causing a general blood-poisoning without local lesion. But the practical evidence in favour of this view is small, and it is very doubtful if it is really true of cattle.

In those exposed to infection by the inhalation of dust charged with anthrax-spores, as wool-sorters, the form of disease is usually bronchial. In all the cases investigated by the writer this was the form observed; and further investigation of wool-sorter's disease by others since that time has fully confirmed the observations then made, both as to the form of disease and the microscopic lesions.

1. Bronchial Form.—**Wool-sorter's Disease.**—In this form inoculation takes place by the inhalation of dust from wool or hair containing the spores of the anthrax-bacillus. The site of inoculation is in the lower part of the trachea and the large bronchi. Local lesions closely resembling those of malignant pustule are here produced in the mucous membrane, and thence the virus spreads by the lymphatics to the bronchial and mediastinal glands. These become greatly swollen, and often the seat of hæmorrhages. Thence infection, with intense inflammatory œdema, spreads to the connective tissue of the mediastinum, and possibly upwards to the neck, to the root of the lungs, and

sometimes to the pericardium. Although the pleura are rarely inflamed, the pleural sacs become filled with serum, and the lungs collapse. Such are the constant lesions. But the virus may spread to other organs, if once it enters the blood, and may then produce hæmorrhages or inflammatory exudations in them, with consequent symptoms. The alimentary canal, the peritoneum, the brain and its membranes, may be especially affected. But death often occurs before they have become involved.

ANATOMICAL CHARACTERS. — Marked lividity is common, often being present even during life. Some swelling may be seen in the lower part of the neck, though rarely. The blood is dark-coloured, and coagulates imperfectly.

On opening the thorax, some emphysema may be present in the anterior mediastinum. But constantly there is seen a diffuse infiltration of the mediastinal tissues, either pale and gelatinous, or deeply blood-stained, or with scattered hæmorrhages. Both pleural cavities contain a large quantity of fluid, if the two layers were not previously adherent; the fluid is usually pale and clear, or very slightly turbid. Rarely it is blood-stained. The quantity in each pleura may be from two to four pints. The serous membrane is usually free from all trace of inflammation, though this occurs in rare cases. The pericardium also often contains an excess of fluid. If inflammation is present, it rarely extends to the epicardium.

The lungs are collapsed; they may show minute scattered hæmorrhages, or small patches of broncho-pneumonia, but this not commonly.

The mediastinal and bronchial glands are greatly swollen, and the hæmorrhage in them may make them look like clots. Extensive infiltration of the whole of the connective tissue around them is present, reaching sometimes up into the neck.

The fluid squeezed from this tissue may contain bacilli, but both here and in the pleural fluid they may be very scanty.

On opening the trachea and bronchi, they are found to contain blood-stained frothy fluid. Towards the lower part of the trachea and in the main bronchi the mucous membrane is irregularly swollen and blood-stained in patches. In addition, hæmorrhages are seen in the mucous membrane, forming raised spots. This condition is usually limited to the main bronchi, but may extend into their primary divisions.

On microscopical examination, the most marked changes correspond to the hæmorrhagic areas. The hæmorrhage lies for the most part immediately beneath the basement-membrane, which may have ruptured, the blood forming a layer beneath the detached epithelium. It may also penetrate deeply into the mucous and submucous coats. All the tissues beneath and around are infiltrated with serum, and their tissue-elements thus separated, but not usually necrotic. The blood-vessels are dilated, but leucocytic emigration is scanty. Dense masses of bacilli are found in the exudation, and escaping to the surface. They also surround and extend in the lymphatics, perivascular and other, and may be traced in them to the deeper lymphatic plexuses. Similar masses of bacilli may also be seen in the superficial layers of the mucosa, where as yet little or no inflammation has occurred. They often lie immediately beneath the basement-membrane. Little or no catarrhal change is seen, the

epithelium simply desquamating; if catarrh is present, it is usually of older date.

In the bronchial glands, the condition is often masked by the extensive hæmorrhage. Bacilli are

FIG. 1.—Anthrax-Bacilli. *a*. In heart-wall of a cow. *b*. In the pulmonary capillaries of a cow. *c*. In the human bronchial mucous membrane, in a case of 'wool-sorter's disease.' $\times 800$ diam.

found, often scantily, especially in the lymph-sinuses of the cortex. Sometimes they are very abundant, and may then also appear in the capillaries.

FIG. 2.—Bacilli from the fluid exuded from the lung in a case of internal anthrax. *a*. Red blood-corpuscles. *b* and *c*. Large granular corpuscles from the lung. *d*. Bacilli of various lengths, containing highly refracting granules, or fully formed spores. \times about 700 diam.

In the lungs, scattered patches of hæmorrhage may be present, mainly due to the inhalation of blood from the bronchi. These may also produce areas of lobular collapse and broncho-pneumonia.

But for the most part, nothing but the general collapse and congestive œdema are found in the lungs, and bacilli are often not to be discovered, except here and there in the lymphatics near the root. This common absence of bacilli in the pulmonary capillaries proper is in marked contrast with the condition usual in cattle.

In other organs, the changes are diverse, and may be absent. There is not usually much cloudy swelling or other indication of septicæmia, though they may be present. Minute hæmorrhages are often apparent; or, in the pia mater, and generally in serous membranes, diffuse extravasations. In the stomach and intestines submucous exudation and scattered hæmorrhage may occur.

For the most part, the spleen is but slightly swollen. Examination of the blood and of other organs, such as the kidney, in which bacilli are commonly abundant in many animals, is usually attended with negative results, though in some cases bacilli may be found by careful search. Inoculation with these parts or with the blood may also produce no effect. But if susceptible animals are inoculated with the bronchial fluid, or other parts which contain bacilli, typical anthrax is produced.

The lesions in the trachea and bronchi are essentially similar to the skin-lesion in malignant pustule, allowing for differences in structure.

The multiple nature of the lesion in the bronchi and trachea is no doubt explained by the ready spread of the bacilli in the lymphatics of the mucous membrane, and by secondary inoculation with the bacilli exuded on its surface.

The pleural exudation, which forms so constant a feature in typical cases, usually without any inflammation of the serous membrane, is probably due to the enormous and rapid obstruction of the lymph-channels in the glands and mediastinum. The swelling and obstruction of the bronchi must also aid the collapse of the lungs, by preventing the entrance of air.

A knowledge of these facts is of essential importance in relation to treatment.

SYMPTOMS AND COURSE.—While presenting considerable variety in the additional symptoms and mode of termination, nearly all cases present characteristic features due to the peculiar lesions just described. To these may be added the effects of nerve-irritation, especially of the phrenic nerves, the vagi, and the cardiac and pulmonary plexuses.

Only the more important of the clinical phenomena will be described. The earlier symptoms are usually great lassitude, chilliness, sometimes with rigors, and mental depression, sometimes with insomnia. Headache, dizziness, and nausea are often present. Vomiting may occur early, and be a prominent symptom, possibly due to the nerve-irritation above mentioned. With these or other symptoms there is commonly complained of at an early period a peculiar sense of constriction of the chest, especially at the lower part, and a want of breath. This is sometimes accompanied by marked pain or cramp-like feeling, and is aggravated by exertion. Cramps and tingling sensations in the limbs, palpitation, flushings, and perspirations may occur.

After a period varying from one to five days, during which there may be intervals of improvement, there ensue more severe symptoms, and the patient has to leave work and often to take to bed. These more pronounced symptoms include greatly

increased prostration, accelerated and difficult respiration, usually rise of temperature, and a rapid and feeble pulse. In addition, the sense of painful constriction of the chest is often marked. Cough, which may be slight or almost absent at first, now usually becomes marked; it is dry, hacking, and painful. The sputa are usually scanty, frothy, and blood-stained, but may become abundant and hæmorrhagic. Bacilli may be found in the sputa.

Sometimes death occurs from syncope within twenty-four hours after the patient gives up work, nothing but the dyspnoea and cyanosis being observed.

More commonly the dyspnoea and cyanosis increase, the face becomes pallid or livid, the pulse and respiration are accelerated, and the general symptoms become more marked. Headache is sometimes intense; vomiting may be frequent and urgent, and indications of the involvement of other organs show themselves. Of these, gastro-intestinal irritation is frequent; there may be severe colic; hæmorrhage from the bowels may occur, though infrequently. In fact, the disease may assume the gastro-intestinal form. Or the cerebral or spinal centres may be especially involved; hence delirium and somnolence, more rarely convulsions or tetanic spasms. Death may be preceded by coma, or the patient may be conscious to the last.

In many cases scattered hæmorrhages in the skin or subcutaneous tissue, or diffuse discolourations, are observed during life, but they may be entirely absent. In rare cases typical carbuncles have been observed. Remissions sometimes occur, to be followed by more marked prostration. In nearly all cases, even if the temperature is high, there is great coldness of the extremities, with indications of asphyxia.

The range of temperature is very variable, and it shows also marked oscillations; but observations on the surface-temperature are not reliable, owing to the great chilling of the surface.

Of the physical signs, those of pleural effusion are the most marked, but the effusion sometimes occurs very rapidly, and may not appear till shortly before death. Bronchitic sounds, &c., may of course also be present.

Even when severe symptoms have developed, recovery may take place. In the cases collected by Spear, four out of twenty-three recovered. And in many cases which presented marked initial symptoms, and from their relations to infection were in all probability cases of the disease, the more severe symptoms did not develop. In some, secondary changes in the lungs appear to have caused death at a much later period.

Death usually occurs within from two to six days from the onset of marked symptoms. Eleven of the twenty-three cases mentioned died within three days. Only two died at eight days, and these from septic complications.

When recovery occurs, convalescence is often very prolonged.

TREATMENT.—Prophylactic measures are by far the most important. Of these the careful separation and disinfection by superheated steam of all wool or hair which shows suspicious characters, such as excess of blood-staining, dirt, &c., or which comes from districts where anthrax is common, are of prime importance. The characters and origin of such wool or hair are well known to those engaged in such trades. Next in importance are the

thorough ventilation of the rooms in which the wool is sorted, and the greatest care in washing the hands, changing the clothes, &c. The effect of such precautions, which were first enforced in 1884, has been to reduce the mortality from the disease in the Bradford district to two per annum during the years from 1884 to 1890 inclusive; whereas in the period of ten months at the time of our inquiry in 1879-80 there were nine cases of malignant pustule with two deaths, and twenty-three cases of internal anthrax with nineteen deaths.

Of the treatment to be adopted when the fully pronounced symptoms are present, little can be said. The evacuation of the fluid from the pleuræ is certainly indicated, and the internal administration of strong meat-broths, stimulants, and cardiac tonics, especially straphanthus. But when once the virus has entered the blood, it is probable that little can be done beyond dealing with complications as they arise.

Prophylactic inoculation does not appear to be applicable to man. Moreover, it does not appear that one attack affords protection in man, since internal anthrax has been fatal in some who have suffered previously from malignant pustule. For some points bearing on the subject of protective inoculation, and the toxins and antitoxins of anthrax, see IMMUNITY.

2. Gastro-Intestinal and other Forms.—Of the other forms of internal anthrax it need only be said that they appear to be far rarer, and that their symptoms and treatment correspond with those described above, when they occur as complications of the bronchial form. A few cases are on record in which the disease has followed eating parts of animals which have died from anthrax, as flesh, liver, &c. In these cases lesions were found in the stomach, intestines, &c., corresponding to those described in the bronchi in wool-sorter's disease; the mesenteric glands showing a condition resembling that of the bronchial glands.

The symptoms in such cases are mainly abdominal, and the disease is usually rapidly fatal.

It is questionable whether many of the cases which have been described as gastro-intestinal, or *mycosis intestinalis*, and especially where there is a phlegmonous gastritis, are not due to other bacteria. In none of the cases which the writer has examined have anthrax-bacilli been found; in some only micrococci were present; in others, bacilli which, though bearing a superficial resemblance to anthrax-bacilli, proved to possess entirely different characters. Microscopic examination and inoculation of animals can alone decide in any particular case.

W. S. GREENFIELD.

PUTRID FEVER.—A synonym for typhus fever. See TYPHUS FEVER.

PYÆMIA (πύον, pus; and αἷμα, blood).—SYNON. : Purulent Infection : Fr. *Pyohémie*; Ger. *Pyohämie*; *Pyämie*.

A condition of blood-poisoning which gives rise to fever, accompanied either by severe visceral inflammations and congestions, or by certain local lesions, which are chiefly venous thrombosis, embolic abscesses in the viscera, acute suppurations of the serous membranes and joints, multiple abscesses in the connective tissue, and eruptions upon the skin. The disease is usually, but not always, sequential to a wound or injury.

PYELITIS (πύελος, a vessel).—SYNON. : Fr. *Pyélite*; Ger. *Nierenbeckenentzündung*.—Inflammation of the pelvis of the kidney. See KIDNEYS, Diseases of, p. 834.

PYLEPHLEBITIS (πύλη, gate = *porta*; φλέψ, a vein).—Inflammation of the branches of the portal vein, often associated with thrombosis. See PORTAL THROMBOSIS.

PYLORUS.—See STOMACH, Dilatation of, Inflammation of, Malignant Disease of, and Neuroses of.

PYOGENIC BACTERIA.—While nearly all the pathogenic bacteria possess the power, under certain conditions, of initiating purely pyogenic processes in place of or in addition to their specific lesions (e.g. *Bacillus tuberculosis* and *Pneumococcus*), there are a few organisms which commonly express their pathogenicity by the formation of pus; these are usually grouped together under the title of *Pyogenic Bacteria*, as distinct from those which only occasionally assume a pyogenic rôle.

The most important of the pyogenic bacteria in point of frequency are the *Staphylococcus pyogenes aureus*, the *Staphylococcus pyogenes citreus*, the *Staphylococcus pyogenes albus*, and the *Streptococcus pyogenes longus*; next, and of less constant occurrence, the *Bacillus pyocyaneus*, the *Bacillus* of Friedlander, and the *Bacillus coli communis*; and lastly, and usually in certain well-defined situations, the *Gonococcus*, the *Koch-Weeks bacillus*, and others.

The members of the last of these groups will be found under special headings, or the headings of the specific diseases with which they are causally associated.

Staphylococcus Pyogenes Aureus.—This organism occurs in pus as small zoogloea-masses, each containing from five to twenty spherical bodies, which have remained in close apposition after the completion of the process of fission. These masses of cocci are arranged for the most part between the pus-cells, but occasionally some may be demonstrated within the cells. The individual cocci measure from 0.6 to 0.9 μ in diameter. They stain readily with all the basic aniline dyes, and retain their colour perfectly when treated by Gram's method. The *Staphylococcus aureus* is a non-motile, non-sporing, liquefying, facultative anaërobe, readily cultivated upon nutrient media both at 22° C. and at 37° C.—this latter being the optimum temperature. Its thermal death-point is 58° C. In spite of the fact that spore-formation does not occur, the organism possesses considerable powers of resistance; a solution of perchloride of mercury (1 : 1000) does not effectually destroy the coccus in 24 hours, while a solution, five times as strong (1 : 200), of the same germicide requires from fifteen minutes to one hour to effect its destruction. The action of desiccation and light are also resisted for considerable periods. Cultivations upon artificial media will retain their vitality for years. The chromogenicity of the organism is best brought out in cultivations upon solid media, which have been freely supplied with oxygen and incubated at a temperature of 24° C.

Cultural Characteristics.—In gelatine 'stab-culture' the growth at first shows along the track of the needle as a faint whitish line composed of minute spherical colonies, discrete or confluent,

which rapidly increase in size. By the end of about three days liquefaction of the medium begins to form a broad funnel filled with turbid gelatine. The liquefaction then proceeds rapidly, some of the growth sinking to the apex of the funnel and gradually becoming bright orange-yellow in colour. In gelatine 'shake-cultures' growth occurs uniformly throughout the substance of the medium, liquefaction commencing from the surface. No formation of gas takes place in sugar-gelatine. In bouillon at 37° C. a uniform turbidity of the medium is observed in less than 24 hours, and may be accompanied by slight pellicle-formation. Eventually the greater part of the growth is deposited and assumes a yellowish tint. The indol-reaction can usually be obtained in from 48 to 72 hours. Upon the surface of nutrient agar, a thick, spreading, moist, shining, cream-coloured layer forms, which afterwards becomes orange-coloured. Upon the surface of inspissated blood-serum the growth resembles that upon agar, the medium not being liquefied. Litmus-milk is coagulated by the coccus in the course of its growth, and becomes strongly acid in reaction. Upon sterilised potato, especially if cultivated at the ordinary temperature of the laboratory, the coccus produces a thick whitish layer which soon becomes yellowish in colour and finally bright golden.

The *Staphylococcus aureus* is pathogenic for the rabbit and the mouse (especially the white mouse), the result of inoculation varying, among other factors, with the method employed. Subcutaneous injection is usually followed by abscess-formation, sometimes by septicæmia. Intravenous injections if the dose is fairly large, usually result in death from general septicæmia. By appropriate means peritonitis, meningitis, arthritis or osteomyelitis may be produced.

***Staphylococcus Pyogenes Citreus*.**—This organism differs from the *Staphylococcus pyogenes aureus* only in the production of a lemon-coloured instead of an orange pigment. It is said, too, that the *Staphylococcus citreus* is less virulent than the *aureus*.

***Staphylococcus Pyogenes Albus*.**—This is morphologically identical with the *Staphylococcus aureus*. Culturally it only differs in that its growth is creamy-white. Its virulence, as a rule, is markedly less than that of the *aureus*.

***Streptococcus Pyogenes Longus*.**—**SYNON.**: *Streptococcus Erysipelatosus*. The *Streptococcus longus* occurs in pus and serum, as chains of spherical cocci, but sometimes as diplococci, lying free between the leucocytes, and never within them. The chains vary in length, containing from ten to fifty cocci, and are frequently convoluted; the individual organisms are usually small, averaging 0.5 μ in diameter, though some are occasionally quite twice that size, the latter being probably just about to undergo fission. This streptococcus stains readily with the basic aniline dyes, and, like the pyogenic staphylococci, retains the stain after treatment by Gram's method. The *Streptococcus longus* is a non-motile, non-sporing, non-liquefying facultative anaërobe, which, under laboratory conditions, is best cultivated at the temperature of the body; it will also grow though with difficulty at the ordinary temperature of the room. Its vitality is not great, cultivations upon artificial media dying out in the course of a few weeks; its virulence, too, is quickly lost, and in like manner

its resistance to germicidal agents is but slight—e.g., 2-per-cent. solution of phenol is sufficient to completely destroy the *Streptococcus* within a few minutes. Its thermal death-point is 54° C.

Cultural Characteristics.—Upon the surface of nutrient gelatine a scanty growth of minute, raised, hemispherical, whitish, opaque colonies appears in 48 to 60 hours. The colonies are scattered and discrete, and increase but little in size with age. The medium is not liquefied. Upon the surface of agar the colonies remain discrete, and closely resemble those formed upon gelatine. They are, however, larger, more opaque and greyish, and the base of each colony is frequently surrounded by a delicate halo. The growth upon inspissated blood-serum is similar to that upon agar. Upon the surface of potato, the growth is usually described as 'invisible,' and, when most evident, only appears as a moist-looking area. In bouillon, growth occurs as fine flocculi which settle on the most dependent part of the wall of the tube, or sink to the bottom; the supernatant medium remains clear. The indol-reaction is absent. Luxuriant growth takes place in litmus-milk, accompanied by an acid reaction; clotting may or may not be observed. This *Streptococcus* is pathogenic for the rabbit, guinea-pig and mouse. When injected subcutaneously a local abscess is usually produced, but apparently identical races of streptococci differ in virulence to such a degree that the result of similar inoculations may vary from a transient erythema to death from streptococcic septicæmia.

***Bacillus Pyocyanus*.**—The *Bacillus pyocyanus* was first isolated from blue pus, the colour of which was due to this bacillus. The *Bacillus pyocyanus* occurs as short slender rods with rounded ends, often so short as to resemble cocci; also united in pairs or short chains, and in long threads. Individual elements average 0.3 to 1 μ in diameter by 2 to 3 μ long; are actively motile, and each rod is furnished with a single terminal flagellum. The bacillus stains well with all the ordinary aniline dyes, but is completely decolourised when treated by Gram's method. The *Bacillus pyocyanus* is a non-sporing, liquefying, facultative anaërobe. It grows readily on artificial media at the room-temperature, but its optimum temperature is 37° C. Its thermal death-point is reached at 55° C. The formation of pigment only takes place in the presence of oxygen; at least two pigments are elaborated, the one yellow, *pyoxanthose*, the other blue, *pyocyanin*, and to these pigments the so-called 'blue pus' owes its colour.

Cultural Characteristics.—In gelatine plate-cultures the colonies rapidly develop as small flat plaques, having a dark green central spot surrounded by a delicate radiating lighter zone, the surrounding medium being fluorescent. Liquefaction commences at about three days in the form of a funnel. In gelatine stab-cultures liquefaction at first proceeds in the form of a funnel, the liquid gelatine being turbid and fluorescent, and containing whitish flocculi in suspension. Later the liquefaction extends to the edges of the tube, the flocculi sink and the liquid portion is separated from the solid gelatine by a horizontal line, the deeper parts of the medium away from the air lacking the fluorescence of the upper portion. Shake-cultivations in sugar-gelatine do not give rise to the formation of gas. Upon the surface of agar a moist whitish layer develops, which later becomes greenish in colour,

while the medium itself is fluorescent and appears green by reflected, and orange by transmitted light; subsequently this colour darkens to blue-green or black. Upon the surface of inspissated blood-serum a thick moist layer appears, dirty white at first but afterwards becoming brown, and the medium itself is liquefied. In bouillon, growth occurs as a uniform turbidity accompanied by the formation of a delicate pellicle of a light greenish colour. The indole-reaction can be obtained in about seventy-two hours. Litmus-milk is at first clotted, showing an acid reaction; later the coagulum is dissolved. Upon the surface of potato a light brown or green slimy layer is formed confined to the needle-track, and the substance of the medium is discoloured. The *Bacillus pyocyaneus* is pathogenic for the rabbit and the guinea-pig. Subcutaneous inoculation of a small dose is followed by local abscess; a large dose causes œdema, purulent infiltration of the tissues, and death. Intraperitoneal injections usually cause death in from twenty-four to thirty-six hours from general septicæmia.

Bacillus of Friedländer.—**SYNON.** : *Pneumobacillus*.—This bacillus was first isolated from the lung-tissue in a case of lobar pneumonia. The bacilli, as seen in pus and sputum, are short oval rods, arranged singly, in pairs, or even in short chains of from four to eight individuals; occasionally bacilli are so short as closely to approach the spherical—so closely so, in fact, that the organism was originally described as a coccus. Each element, in combination, is surrounded by a clear refractile space, indicating the presence of a capsule similar to that possessed by the pneumococcus, and capable of demonstration by identical staining-methods. When cultivated upon artificial media the pneumobacillus loses its capsule, while the variations in size and shape of the rods are so marked as to render the polymorphism of the organism one of its most striking characters. The bacillus stains readily with all the aniline dyes, but is completely decolourised when treated by Gram's method. The organism is a non-motile, non-sporing, non-liquefying, facultative anaërobe; easily cultivated upon artificial media, and growing freely at the room-temperature, although its optimum temperature is one more nearly approaching to that of the body. Its thermal death-point is reached at 55° C. It possesses considerable vitality. Cultivations upon artificial media, more than two years old, have yielded successful subcultures.

Cultural Characteristics.—In gelatine streak-cultures the pneumobacillus produces a thick elevated opaque white growth with a smooth shining porcelain-like surface. In gelatine stab-cultures it shows as a typical nail-growth, the head being composed of a hemispherical mass of the size of a split pea, and the shaft, of discrete or confluent colonies down to the extremity of the needle-puncture. A shake-culture in sugar-gelatine demonstrates the abundant production of gas. On the surface of slanted agar a growth is produced resembling that upon gelatine, but somewhat more slimy, and showing a tendency to slip down the inclined surface to the bottom of the tube. Upon inspissated blood-serum a similar condition is produced. The medium is not liquefied. Bouillon exhibits a uniform turbidity in about twenty-four hours, and the presence of indol may be demonstrated in from forty-eight to seventy-two hours. Upon the surface of potato a slimy buff-coloured

growth appears which in the course of a few days becomes a dirty brownish-yellow, while the substance of the medium assumes a greyish tint. Litmus-milk shows clotting in from twenty-four to forty-eight hours, accompanied by the production of a strongly acid reaction. Friedländer's bacillus is pathogenic for ordinary animals, though in varying degrees. When inoculated under the skin of the mouse death ensues in from three to five days from general septicæmia, and the organism can be recovered in pure culture from the blood in the heart. Inoculations into the subcutaneous tissue of the guinea-pig are usually followed by similar results, although recovery occurs fairly often. The rabbit is still more resistant, and recovery is the rule. Cultivations upon artificial media appear to retain their virulence unimpaired for long periods.

Bacillus Coli Communis.—*See p. 121.*

JOHN EYRE.

PYONEPHRITIS.—Inflammation of the kidney, leading to the formation of abscess. *See* KIDNEYS, Diseases of, pp. 821, 823, 834.

PYOPNEUMOTHORAX.—A morbid condition of the pleural cavity, in which it contains both pus and gas. *See* PLEURA, Diseases of.

PYORRHOEA ALVEOLARIS.—*See* TEETH, Diseases of.

PYRENEES.—*See* BIARRITZ; BAGNÈRES-DE-BIGORRE; EAUX-BONNES; EAUX-CHAUDES; LUCHON and PAU; and CLIMATE, Treatment of Disease by.

PYREXIA (πύρ, fire; and ἔχω, I have).—This word is sometimes employed as a synonym for fever; but it is more properly applied to the elevation of the body-heat which is one of the phenomena of fever. *See* FEVER; and TEMPERATURE.

PYRMONT, in Germany.—Iron waters and salt waters. *See* MINERAL WATERS.

PYROMANIA.—A name which has been given to insanity when the patient manifests a propensity to incendiarism. Its claim to be regarded as a special form of insanity has not been established. *See* INSANITY.

PYROSIS (πυρῶς, I burn).—**SYNON.** : Water-brash; Fr. *Pyrosis*; Ger. *Sodbrennen*.

This term was originally applied to the eructation of strongly acid fluid from the stomach accompanied by a burning pain at the epigastrium. By many writers the use of the term has been extended so as to include the expulsion (1) of swallowed saliva collected in the œsophagus above its spasmodically contracted lower end, and (2) of neutral or slightly acid fluid from the stomach some hours after the chyme should have passed into the duodenum. Moreover, the strongly acid fluid to which the term was originally limited is not always of the same character. In some cases the acidity is due to free hydrochloric acid; in others, to butyric and other organic acids. A term of such uncertain meaning should certainly be discarded.

H. MONTAGUE MURRAY.

PYSTJAU, in Hungary.—Thermal sulphur-waters. *See* MINERAL WATERS.

PYURIA (πῦον, pus; and οὔρον, the urine).—A name for a condition of the urine in which it contains pus. *See* URINE, Morbid Conditions of.

Q

QUARANTINE (Ital. *quaranta*, forty). —
SYNON. : Fr. *Quarantaine*; Ger. *Quarantäne*.

DEFINITION.—The enforced isolation of individuals and certain objects coming, either by sea or by land, from a place where dangerous communicable disease is presumably or actually present, with a view of limiting the spread of the malady. The objects liable to quarantine include—on the assumption of their being apt to carry the contagion or infection of the disease—the luggage and personal effects of the individuals isolated, certain articles of merchandise, and ships; and, in land-quarantine, carriages and other vehicles. Sometimes entire communities and districts are subjected to quarantine.

In Great Britain and Ireland quarantine was until 1896 carried out under an Act of Parliament passed in the reign of George IV. (6 George IV. cap. 78). It was practised, and that only to a limited extent, solely with a view of relieving our maritime commerce from disabilities which would else be imposed upon it by other countries, in which quarantine is regarded as an essential part of the public-health administration. The regulation of quarantine was not a function of the department of the government which is concerned with the sanitary administration of the kingdom (the Local Government Board), but of the Privy Council, aided by the Board of Trade, the subject being dealt with as an international commercial question. In what follows an authoritative official memorandum of the late Dr. E. C. Seaton (formerly medical officer of the Local Government Board) on the subject is closely adhered to.

The Quarantine Act provided for land-quarantine and the quarantine of inland waters, as well as for maritime quarantine—internal and external quarantine, so to speak. It does not appear that internal quarantine has ever been enforced in this country. Since the Act was passed maritime quarantine alone has been practised, and this has been applied to three diseases only, all of them infectious diseases of foreign origin, namely, plague, cholera, and yellow fever. Of plague there has been, until quite recently, no question in English ports for fifty years, except a slight alarm in 1879, consequent upon an outbreak in South-eastern Russia in the province of Astrakhan. Against cholera quarantine had not been enforced since 1858, its futility as a precautionary measure in this country having been abundantly manifested. Yellow fever was the sole disease subjected to it in our ports, and this, as already stated, not from the medical necessity, but from the commercial exigency of the case. The only quarantine establishment remaining in England—that at the Motherbank—was maintained in respect of that disease. Infectious diseases habitually current in this country, such as small-pox and scarlet fever, notwithstanding that the phraseology of the Quarantine Act covered any 'infectious disease or distemper,' had always been in practice exempt from quarantine, and dealt with under the general sanitary law of the kingdom. It appears to have been recognised that measures, primarily designed to prevent the introduction into the

country of diseases only coming to us from abroad, and which involved international considerations, would be misapplied if used for the purpose of preventing the importation of diseases, ordinarily existing here, the limitation of which, and not the exclusion, could alone be in question.

In 1896 the Quarantine Act of George IV. was repealed, and the measures which had been applied to cholera were extended to yellow fever and plague. Before discussing these measures we may conveniently refer to the attitude of foreign Powers to the subject of quarantine.

In reference to cholera, foreign countries have, during recent years, shown a readiness to modify the requirements of quarantine, and substitute shorter periods of detention for those formerly insisted on. Conferences between representatives of the Powers have been held at Paris in 1852, Constantinople in 1866, Vienna in 1874, Rome in 1885, Venice in 1892 (the conclusions of which were subsequently modified at Paris), and Dresden in 1893, when Great Britain was represented by Mr. Strachey, the resident Minister at Dresden, Sir Richard Thorne Thorne, K. C. B., Medical Officer of the Local Government Board, and Mr. H. Farnall, C.M.G., of the Foreign Office. A further conference was held in Paris in 1894 for the purpose of devising measures for preventing the spread of cholera by way of the Red Sea and the Persian Gulf. Inasmuch as the conclusions of the conference of 1893 have been accepted by the English Government, it will be convenient to give a brief account of their nature.

I. Notification to Foreign Governments.—A cholera-centre¹ is to be notified to all the Governments signing this agreement. Isolated cases are not necessarily to be notified. Communications concerning progress of disease are to be made at least once a week.

II. Circumstances under which Districts are to be deemed Infected.—A district is to be considered infected when the existence of a cholera-centre has been officially stated; no longer infected when no deaths or fresh cases have occurred within five days, and the measures for necessary disinfection have been taken.

[The word 'district' is applied to any part of a country placed under a well-defined administration.]

III. Limitation to Infected Districts of Preventive Measures.—Measures for limiting the spread of the epidemic are only to apply to products of the infected districts, and not then if the products have left the country five days before the outbreak began.

IV. Merchandise or Dangerous Articles considered from the point of view of (1) Prohibition of Importation and Transit and (2) of Disinfection.

¹ The term actually used is *foyer*, and is thus referred to by the *Lancet* of July 15, 1893, p. 152: 'Practically the use of the term *foyer* means that if there are isolated cases of cholera the French Government will not notify; but if cases are grouped together and form a sort of kernel—a centre, a focus, radiating, scattering around the germs of disease—then the French Government will notify.'

1. The only things to be forbidden are: (a) body-linen, clothes in use, bedding (except when considered as luggage or when moving from one house to another, when they are to be specially dealt with); (b) rags and drills; but the following are not to be prohibited: rags compressed by hydraulic power, which are forwarded as wholesale merchandise and labelled with name of the place of destination, &c.; and clean clippings coming direct from spinning, weaving, making-up, or bleaching establishments; artificial wool, and fresh paper-havings. Goods are not to be detained in quarantine on the frontiers of countries.

2. Disinfection of baggage is to be obligatory in respect of such things as clothes, dirty linen, &c., coming from an infected district, if the local sanitary authority consider them contaminated. Merchandise is to be disinfected so as to damage as little as possible; each State is to arrange the method of disinfection. Letters or printed matter are not to be disinfected.

V. *Measures at Land-Frontiers.*—*Railways, Travellers.*—Infected carriages are not to be retained at frontier towns—if soiled, they are to be detached for disinfection wherever possible. Land-quarantine is no longer to be established. Only persons suffering from cholera and those attacked with a choleraform disease are to be detained. The officials of the railway are to see if all travellers are well—if ill, a medical man is to be called in. Inspection is to be made, if possible, at the Custom-house stations so as to hinder travellers as little as possible. On arrival at destination, travellers coming from infected districts are to be subject to five days' observation dating from the time of their departure from such districts. This, of course, does not apply in the case of Great Britain, which has no land frontier.

Special measures may have to be taken with regard to bohemians, vagabonds, emigrants, and persons travelling in parties.

VI. *Regulation of Frontier-Traffic.*—Frontier-traffic arrangements are to be left to special measures to be taken by the neighbouring (adjoining) countries.

VII. *Waterways.*—The arrangements for regulating traffic are to be left to the States on river banks. Those regulations in force in Germany in 1892 are recommended.

VIII. *Measures to be taken at Ports.*—A ship is to be considered *infected*, which has cholera on board or if it has had fresh cases of cholera during the preceding seven days; to be considered as *suspected* where there have been cases on board though not during the last seven days; to be considered as *healthy*, though coming from an infected port, if having had neither case of cholera nor death from cholera on board before the departure, during the voyage, or since arriving.

Infected ships are to submit to the following:—

(1) The sick are to be disembarked and isolated.
(2) The others are to disembark and remain under observation during a period not exceeding five days. The signature of Great Britain to the Dresden Convention was conditional that for the purposes of England the 'observation' should, both for infected and suspected ships, be in the homes of the persons under observation instead of in any specially provided place.] (3) Dirty linen and clothes, &c., belonging to passengers are to be disinfected, if

deemed contaminated by the sanitary authority, as well as the ship or part of ship infected.

Suspected ships are to submit to—

(1) Medical inspection; (2) disinfection; (3) removal of bilge-water after being disinfected, and substitution of good drinking-water in place of that stored on board.

It is recommended that passengers should be under observation not more than five days from the date of arrival, and that the disembarkation of the crew should be delayed.

Healthy vessels are to be allowed free pratique. It is, however, permissible that the authority of the port may in the case of healthy vessels adopt the same measures as in the case of suspected vessels, except that the period of observation (five days) should date from the time of departure of the vessel instead of the date of arrival.

The authority of the port is to take into consideration, before ordering these measures to be adopted, the presence of a doctor and of a disinfecting-stove on board the vessel. Special precautions are to be taken on vessels crowded with emigrants, and insubstantial vessels. Goods arriving by sea can only be treated similarly to those arriving by land. All ships refusing to submit to the port arrangements are free to put out to sea. They may only unload after the necessary precautions have been taken—(1) isolation; (2) removal of bilge-water; (3) substitution of good water. No passengers are to disembark unless willing to submit to the port regulations. Every country should provide at least one port on each of its coasts with the organisation and apparatus for receiving ships whatever their sanitary state. Coasting vessels are to be subject to special regulations, to be arranged between the countries interested.

Special measures are to be taken with regard to vessels coming from an infected port and going up the Danube. Until the town of Soulina is provided with a good water-supply, all boats going up the river are to be subjected to rigorous hygienic measures.

Overcrowding of passengers is to be strictly forbidden.

In reference to plague, a conference of the Powers was held in Venice in 1897. The principal questions considered were—(a) the measures for preventing the spread of plague out of Europe, including the measures to be taken on board pilgrim-ships; and (b) the measures to be taken in Europe. The principles which governed the decisions of the Dresden Conference in respect of cholera were again accepted, as applicable to plague, some modifications being made in view of the longer incubative period of the latter disease. Thus infected vessels were made to include vessels on which disease had occurred within ten days of arrival.

It is interesting to observe that, while foreign countries are thus agreeing to regulations which approximate in some degree to those which are in force in Great Britain, British colonies, having independent control in respect of this subject, maintain a more rigid system of quarantine, and do not limit its application to diseases which in this country are subject to the quarantine law. Thus Malta, Gibraltar, and Cyprus, as well as the more distant colonies, adhere to the old quarantine system; and, indeed, the West Indian colonies have (in 1893) enacted a quarantine law, to which reference may be made as illustrative of the action of the colonies in this respect.

The measures which have, in England, been substituted for quarantine against cholera, yellow fever, and plague, consist in a 'system of medical inspection,' the details of which are set forth in the Order of the Local Government Board, dated the 9th November, 1896, and which include and extend the provisions of antecedent Orders relating to cholera only. This plan differs from 'quarantine' in the following essential respects:—

(a) It affects only (1) such ships as have been ascertained to be, or as there is reasonable ground to suspect of being, *infected* with cholera or choleraic diarrhoea, yellow fever, or plague; no vessel being deemed infected unless there has been actual occurrence of cholera or of choleraic diarrhoea, or of yellow fever or plague on board in the course of the voyage, or during the stay of the vessel in the port of departure, or in a port in the course of the voyage. (2) Ships not infected with cholera or yellow fever or plague, but having passengers on board who are in a filthy or otherwise unwholesome condition. (3) Ships coming from a place infected with cholera, yellow fever, or plague.

(b) It provides for the detention of the vessel so long as is necessary for the requirements of a medical inspection; for dealing with the sick (if any) in the manner it prescribes; and for carrying out the processes of disinfection.

Any person suffering from cholera, yellow fever, or plague must be removed, if his condition admit of it, to some hospital, or other suitable place for that purpose appointed by the sanitary authority; and no person so removed may leave such hospital or place until the medical officer of health has certified that he is free from the disease. If any person suffering from cholera, yellow fever, or plague cannot be removed, the ship must remain subject to the control of the medical officer of health. If any person is certified by the medical officer of health to be suffering from any illness which he suspects to be cholera, yellow fever, or plague, such person may be removed to some hospital, or other suitable place provided by the sanitary authority, or be detained on board the ship for any period not exceeding two days. If within this time he is found to be so suffering, he will be dealt with as above.

(c) It subjects the healthy on board to detention only for such length of time as admits of their state of health being determined by medical examination, or until they have satisfied the medical officer of health as to their names, places of destination, and addresses at such places. The name and address of any such person is to be forthwith given by the medical officer of health to the clerk to the sanitary authority, who is required to transmit the same to the local authority of the district in which the place of destination of such person is situate. If any such person shall within forty-eight hours arrive at a place of destination or address other than that he has given, he is required upon arrival to notify the same to the medical officer of health of the district.

In the case of ships infected with cholera, yellow fever, or plague, or which have come from a place infected with any of these diseases, the medical officer of health may direct the bilge-water to be pumped out before such ship enters any dock or basin; and, on the sanitary authority providing a proper supply of water for drinking and cooking purposes for persons on board the ship, he may direct all casks or tanks on board the ship containing water for the use of such persons to be emptied;

and the master is required to cause these directions to be carried into effect.

In addition to the above Orders, others have been issued from time to time regulating the admission of rags from foreign countries infected with cholera.

The measures for dealing with the sick under the Orders of the Local Government Board are but an adaptation to a particular exigency of the principles of sanitary administration with regard to infectious diseases which are in force under the general sanitary law of the kingdom.

But though quarantine has no present practical existence in this country, and all other infectious diseases are dealt with either under the general sanitary law of the country, or such modification of it as has been just described with regard to cholera, yellow fever, and plague, the machinery of the repealed Quarantine Act, for obtaining information as to the existence of infectious diseases on board foreign-coming ships, is made available for dealing with all diseases of that kind. The questions, which it is the duty of the Customs to put to the masters of all such vessels, embrace all infectious diseases; and, in the event of any such disease being found to exist on board, or to have existed in the course of the voyage, the Customs officer is required to detain the vessel, and to forward the information with the least practicable delay to the sanitary authority of the port. In regard to cholera, yellow fever, and plague, moreover, both the Customs and the sanitary authority have certain powers of detaining the vessel specified in the Order of the Local Government Board above referred to.

The provisions under Articles 12, 13, and 14 of the Order of the Local Government Board of 1896, as to the mode of dealing with persons who may arrive from abroad infected with cholera, yellow fever, or plague, will be better understood if a succinct statement be made of the ordinary provisions of the law with regard to infectious diseases in England. The authorities which have to administer that law, as now existing under the Public Health Act, 1875, are the urban, rural, and port sanitary authorities of the districts into which the whole kingdom is divided. These authorities are empowered—

(a) To provide hospitals or temporary places for the reception of the sick (section 131);

(b) Where a hospital or place for such purpose is provided, to remove thither by order of any justice, on a certificate signed by a legally qualified medical practitioner, any person who is suffering from any dangerous infectious disorder, and is without proper lodging or accommodation, or lodged in a room occupied by more than one family, *or on board any ship or vessel* (section 124);

(c) To make regulations (to be approved by the Local Government Board) for removing to any hospital, to which the local authority is entitled to remove patients, and for keeping in such hospital so long as may be necessary, any persons brought within their district by any ship or boat who are infected with a dangerous infectious disorder (section 125);

(d) To provide and maintain a carriage or carriages suitable* for the conveyance of persons suffering under any infectious disorder (section 123);

(e) To cleanse and disinfect infected premises, and articles therein; to destroy any bedding, clothing, or other articles which have been exposed to infection from dangerous infectious disorder, giving compensation for the same; and to provide all necessary means for the disinfection of infected things (sections 120, 121, 122);

(f) To take proceedings against (1) any person who, while suffering from any dangerous infectious disorder, wilfully exposes himself, without proper precautions against spreading the said disorder, in any street, public place, shop, inn, or public conveyance, or enters into any public conveyance without previously notifying to the owner, conductor, or driver thereof that he is so suffering; or, (2) any person who, being in charge of any person so suffering, so exposes such sufferer; or (3) any person who gives, lends, sells, transmits, or exposes without previous disinfection, any bedding, clothing, rags, or other things which have been exposed to infection from any such disorder; or (4) any owner or driver of a public conveyance who shall not have immediately provided for the disinfection of such conveyance, after it has to his knowledge conveyed any person suffering from a dangerous infectious disorder; or (5) the owner of any house, in which any person has been suffering from any dangerous infectious disorder, who shall knowingly let it or part of it for hire, without having previously disinfected it, and all articles therein liable to retain infection, to the satisfaction of a legally qualified medical man; or (6) any person who, showing for the purpose of letting for hire any house or part of a house, shall make false statements as to the existence of infectious disease therein, or within six weeks previously (the several acts here enumerated constituting offences liable to penalty under the Public Health Act, ss. 126, 128, 129);

(g) To provide mortuaries, and to obtain the removal thither, by order of a justice, of the body of anyone who has died of any infectious disease, which is retained in a room where persons live or sleep, or of any dead body in such a state as to endanger the health of the inmates of the house or room in which it is retained (sections 141, 142);

(h) To make inspection of their district, with a view to ascertain what nuisances exist calling for abatement under the powers of the Act, and to enforce the provisions of this Act in order to abate the same (section 92): a provision which extends to shipping—any ship or vessel lying in any river, harbour, or other water, within the district of a sanitary authority, being subject to the jurisdiction of that authority, in the same manner as if it were a house within such district;

(i) Finally, to appoint a medical officer of health, inspector of nuisances, or several of those officers, according to the needs of the district, and other requisite officers to aid them in the proper and efficient execution of the Act (sections 189, 190). The duties of the medical officer of health and of the inspector of nuisances, when (as is the case in the greater number of instances) the assent of the Local Government Board has to be given to their appointment, are set forth in Orders of the Board dated March 1880.

Beyond the powers conferred upon Sanitary Authorities by the Public Health Act, 1875, other powers of considerable importance in relation to the subject under discussion are given by the notification of Infectious Diseases Act, 1900, and can be

obtained by Sanitary Authorities adopting the provisions of the Infectious Diseases (Prevention) Act of 1890.

Under the former Act, it is obligatory on the authority to require every medical practitioner attending or called in to visit a patient to give notice to the Medical Officer of Health of the district if the patient be suffering from 'small-pox, cholera, diphtheria, membranous croup, erysipelas, the disease known as scarlatina or scarlet fever, and the fevers known by any of the following names—typhus, typhoid, enteric, relapsing, continued, or puerperal,' as well as any other infectious disease which the authority by special resolution may require. The duty of giving notice to the Sanitary Authority also devolves upon the head of the family to which the patient belongs, and in his default the nearest relative of the patient present in the building or being in attendance on the patient, and in default of any such person, the occupier of the building. The notification of cases of plague has recently been made obligatory by a regulation made by the Local Government Board under powers conferred on that Board by the Public Health Act, for dealing with epidemic disease.

Under the latter Act, powers can be obtained for—

(a) Prohibiting the supply within a district of milk from a dairy believed to be productive of infectious disease.

(b) Prohibiting any person from ceasing to occupy a house, room, or part of a house, which has been occupied by a person suffering from infectious disease, without having such house, room, or part of a house, and all articles therein likely to retain infection, disinfected to the satisfaction of a registered medical practitioner, or without giving notice of the previous existence of such infectious disease to the owner, and prohibiting any such person from giving any false answer to the owner or to any person negotiating for the hire of such house, room, or part of a house, as to the fact of there having within six weeks previously been therein any person suffering from any infectious disease.

(c) Prohibiting any person from retaining without the sanction in writing of the Medical Officer of Health or a registered medical practitioner, elsewhere than in a mortuary or in a room not used at the time as a dwelling-place, sleeping-, or work-room, for more than forty-eight hours, the body of any person who has died of any infectious disease.

(d) Prohibiting any person from removing from any hospital or place of temporary accommodation for the sick, except for the purpose of burial, the body of any person who has died from infectious disease, if the Medical Officer of Health or any other registered medical practitioner has certified he is of opinion that it is desirable, in order to prevent the risk of communicating any infectious disease, or of spreading infection, that such body should not be removed from such hospital or place except for the purpose of being forthwith buried. Under such circumstances the body when removed must be taken directly to a place of burial or to a mortuary.

(e) Empowering a justice of the peace on the application of the Medical Officer of Health to order the removal to a mortuary, and to be buried, the body of any person who has died of infectious disease, which has remained for more than forty-

eight hours without the sanction of the Medical Officer of Health or a registered medical practitioner in a room used at the time as a dwelling-place, sleeping-place, or work-room.

(f) Requiring any person who desires to remove in a public conveyance, other than a hearse, the body of any person who has died from infectious disease, to give notice to the owner or driver, and requiring such owner or driver to disinfect the conveyance.

(g) Authorising a justice of the peace to make an order directing the detention in a hospital, at the cost of the authorities, of any person suffering from infectious disease, who would not on leaving such hospital be provided with lodging or accommodation in which proper precautions could be taken to prevent the spreading of the disorder of such person.

(h) Prohibiting the casting into any ash-pit, ash-tub, or other receptacle for the deposit of refuse matter, any infectious rubbish without previous disinfection.

(i) Empowering the local authority to provide, free of charge, temporary shelter or house-accommodation, with any necessary attendants, for the members of any family in which any infectious disease has appeared, who have been compelled to leave their dwelling for the purpose of enabling such dwelling to be disinfected by such authority.

The general powers above enumerated, if exercised duly and with reasonable diligence, are held sufficient to provide for the exigencies which may arise in our ports from the introduction of infectious diseases by ships, whether the disease be current in this country or be of foreign origin not naturalised here; but in the case of a non-naturalised disease, such as cholera, yellow fever, or plague, certain additional securities are taken by the Order of the Local Government Board previously referred to. The general powers, moreover, which are available against the importation of infectious diseases by shipping, are available also, and have on occasions been used, against their exportation in like way to other places.

SHIRLEY F. MURPHY.

QUARTAN (*quartus*, the fourth).—A form of ague, in which the paroxysm returns after an intermission of two days. See **MALARIAL DISEASE**.

QUEENSTOWN, in South of Ireland.—Mild, not relaxing, winter climate. Southern exposure, with shelter. Mean winter temperature 44.1° F. See **CLIMATE**, Treatment of Disease by.

QUINCKE'S DISEASE.—See **ANGIO-NEUROTIC ŒDEMA**.

QUINISM.—SYNON.: Cinchonism; Fr. *Quinisme*; Ger. *Cinchonismus*.

DEFINITION.—A group of symptoms, chiefly connected with the nervous system, produced by the presence of quinine in the blood.

ANATOMICAL CHARACTERS.—In the rare cases in man in which death has been due to quinism, *post-mortem* examination has revealed only the appearances which are common to every case of gradual suspension of respiration, namely, accumulation of dark blood in the internal veins. The same has been found in experiments on animals.

SYMPTOMS.—Large doses of quinine prove fatal by paralysing, firstly, the brain and respiratory

centre; secondly, the heart. Smaller doses may produce various effects on the different organs.

On the whole, quinine does not disturb *digestion*; on the contrary, of all alkaloids tested on this point (of course in the shape of a readily soluble salt), quinine, when given in small doses, alone promotes digestion. Undoubtedly it may often cause vomiting, but for this there may be three reasons—the excessively bitter taste, the effect of a salt not easily soluble when there is a deficiency of normal hydrochloric acid in the stomach, and the unusual influence of quinine on the brain. The first two reasons can easily be avoided, and also the third, if too large doses are not given at once to susceptible patients. The intolerance of the brain soon ceases. It is advisable to tell the patient that vomiting may perhaps follow on the first dose, but that that must not prevent the second being taken—then only a little nausea will ensue, and after the third dose neither. In whooping-cough the first effect of quinine is even to stop vomiting, and improvement of other symptoms follows.

The local irritation of the stomach often depends on the use of the sulphate, while the hydrochloride is easily borne. The sulphate is soluble in about 800 parts of distilled water, the hydrochloride in about 36 parts. Free hydrochloric acid renders them both equally soluble; but when this acid is deficient in the gastric secretion, as is the case in most fevers, the water alone may sufficiently dissolve the hydrochloride, but not so the sulphate. It remains longer than it should as a foreign body in the stomach, and causes irritation. It is an old mistake to prescribe the sulphate, merely because it happened to be the quinine-salt first introduced. The hydrochloride not only irritates the stomach less, but contains also a greater percentage of the base than the sulphate does (83 to 74). These advantages compensate for a somewhat higher price.

The *toxic* effects of quinine, so often mentioned, are the result of large doses. They manifest themselves as deafness, noises in the ears—humming, or resembling the roar of a distant waterfall, the ringing of bells, or the striking of a clock—sickness, heaviness in the limbs, retching, vomiting, and inclination to sleep. Quinine-intoxication can, of course, become dangerous, should the dose have been too large. It shows itself as paralysis of the nerve-centres, and later as paralysis of the heart. Irritation no longer causes the slightest contraction; one could imagine that the heart was poisoned by digitalis: in animals at any rate this condition has been seen by the writer. The skin is pale and cold, and the temperature of the blood, measured in the rectum, may show an enormous depression.

A man of forty-five, who suffered from constipation, took by mistake three drachms of sulphate of quinine, instead of the same quantity of cream of tartar at a single dose. In an hour, pains came on in the head and stomach, giddiness, and general weakness, followed by unconsciousness. The face was pale; the lips blue and cold, as also the limbs; the pulse was still regular, but slow and almost imperceptible; the respiration languid and shallow; the pupils much dilated; vision and hearing almost gone, even after return of consciousness. The medical attendant, who was called after eight hours, wrapped up the whole body in hot towels, and used frictions of the skin and internal stimulants. Improvement ensued after a few hours, and increased

steadily during the following days ; but even on the fifth day the patient was unable to leave his bed for more than half an hour. The general weakness and that of sight and hearing improved, but did not disappear completely for a long time.

In a French military hospital (1885) a soldier swallowed by mistake a 5-per-cent. solution of sulphate of quinine, instead of a similar solution of sulphate of magnesium, equal to twelve grammes (180 grains) of the former. When he complained of the disagreeable bitter taste and of the humming in the ears, the attendant thought proper to swallow the same quantity. Both were taken very ill after less than half an hour ; both suffered from great general apathy and weakness of the heart. The soldier recovered, because a large portion of the solution of quinine was rejected by spontaneous vomiting ; the attendant died before the lapse of four hours, with the symptoms of paralysis of the nervous centres.

Experiments on rabbits and dogs have proved to the writer that, under the influence of large doses of quinine, the respiration is first paralysed, and that life can be preserved at this stage by artificial respiration. Then the heart becomes paralysed by direct influence of the quinine on it, and death ensues. The physician should therefore ask himself, in every case where he considers large doses of quinine desirable, whether an existing or threatening weakness of the respiration or the circulation might prove an objection to the prescription. Speedy death has been observed in typhoid fever in patients or convalescents after about 20 grains of quinine ; and even less may prove dangerous. In such cases 10 grains is a maximum dose, and stimulants should be administered simultaneously, e.g. camphor dissolved in almond oil, in repeated doses of 2-4 grains.

In connection with the influence of quinine on the heart, it must be mentioned here that its action in *small* doses consists of a slight irritation of the organ, probably of its substance. The vagus of the heart has no connection with the effect ; it requires strong doses of quinine to produce any depressing effects on this nerve.

The disorders of *hearing* caused by quinine generally last only for some hours or a few days ; but severe cases are also reported. A man of thirty-seven took 20 grains of hydrochloride of quinine in one dose for ague. The ague left him, but he almost immediately experienced loud noises in the ears, pain in the left ear, heaviness of the head, fits of giddiness, and intense deafness. The ticking of a watch, and the humming of a tuning-fork, were no longer heard when they were pressed to the skull. Eighty grains of salicylate of sodium, taken within five hours (one must ask for what purpose), aggravated all the symptoms. Aural treatment during several months produced but partial improvement. Hearing was slightly better, but still bad.

Investigations on the hearing of healthy men have yielded some interesting results. The temperature of the outer ear, after a dose of 17 grains of hydrochloride of quinine, sank 0.56° C. on an average in twelve experiments within two or two and a half hours. The external meatus and the tympanum were not hyperæmic—on the contrary, they were pale—when the effect of the quinine was at its height. It does not follow that this must always be the case. Some people may get inflammation of the tympanic cavity ; others, again, in-

flammation of the skin, as will be described presently. Inflammatory extravasations were produced artificially in the *canalis cochleæ spiralis* and other parts of the inner ear in a cat, by dosing it with quinine. The writer knows from his own observation that this animal is certainly very sensitive to quinine. It is only in exceptional instances that quinine produces lasting bad effect on the hearing of human beings.

Disturbances of *vision* after large doses of quinine have often been observed. They are caused by direct paralysis of the optic nerve, not by dimming of the refractive media. A. von Graefe has described two cases, both malarial patients. In one case 360 grains had been taken during several weeks ; in the other case 500 grains. In the first case weakness of sight ensued ; in the second case blindness. Both cases lasted several months. Improvement began of itself, and was apparently aided by artificial bleeding from the temples. Many similar cases have since been reported.

The following case is more recent : A woman of thirty-five had aborted, with symptoms of septic endometritis. Cold baths and quinine—80 grains in the course of thirty hours—were employed to control the fever. An eclamptic fit ensued, and immediately afterwards complete loss of hearing and sight. The urine was free from albumen ; the pupils were much dilated and fixed, the refractive media clear, the retina almost bloodless and perfectly insensible to strong light. Consciousness returned a day after the attack ; hearing within the first few days. The blindness of the peripheral parts of the retina remained permanently ; that of the central parts disappeared slowly within six months. Colour-blindness, which had been total when the sensibility to light returned, persisted partly.

It is evident, however, from the reports of cases, that disturbances of vision in patients treated with quinine may often be caused to a great extent by the illness itself, and are then incorrectly attributed to the remedy.

Transient *affections of the skin* after the ingestion of quinine are especially frequent. They present themselves chiefly as eczema, roseola, erythema, urticaria, and purpura. Here only a few instances need be mentioned. Four cases of purpura hæmorrhagica have been described. The most remarkable point about them was their appearance after only small doses ; for instance, after 2 or 3 grains every six hours. According to another medical report, a lady of forty got œdema of the face and limbs, with violent erythematous eruptions, followed by peeling, after taking quinine. A repetition of the medicine caused the same symptoms.

The *kidneys and bladder* do not remain insensible to the alkaloid. Given in large doses it may cause albuminuria and catarrh of the bladder. The latter has appeared with violent fever after 60 grains in one day. Cases have been communicated where a few grains of quinine caused bloody urine, jaundice, and fever, apparently quite independently of the malaria for which it was ordered. This is less singular than the skin-eruptions, as the greater part of the quinine which leaves the body passes through the kidneys. The points of particular interest to us regarding this secretion may be noticed here. G. Kerner recovered 80, 90, and 96 per cent. of the ingested quinine from the urine. The excretion of the hydrochloride of quinine

began as early as fifteen minutes after its ingestion, was most active in the twelfth hour (30 per cent.), and lasted till the forty-eighth hour, when 1 per cent. still appeared. The sulphate of quinine was first traceable in the urine after forty-five minutes, and showed itself—1 per cent. only—till the sixtieth hour. The greater portion of both quinine-salts passes out in the amorphous modification; a smaller part becomes oxidised.

Abortion and premature birth are often attributed to quinine. It seems to the writer, after carefully reading the literature of the subject, that these results are mostly due to the illnesses for which the quinine has been given. As it is a distinct protoplasmic poison, one must admit the possibility that when given in daily long-continued small doses in pregnancy it acts with specific energy on the tender protoplasm of the fœtus, whose gradual decay would lead to evacuation of the uterus. At all events chronic quinism, even of a mild character, is to be avoided under such circumstances, and regarded with suspicion.

Several cases of so-called contrary quinine-effect, that is, a real *febrile attack*, without apparent inflammation of any organ, have been published from time to time. How they originate is altogether unknown. Even relatively small doses may cause them. Blackwater Fever has been attributed to the action of quinine. See BLACKWATER FEVER, p. 143.

Increase of the *general reflex excitability* has also been described as an unusual effect of small doses of quinine. Epileptic patients are said to react to quinine by increase of their fits in number and severity. This would correspond more with the facts derived from experiments on animals, than the assertion that quinine diminishes greatly the reflex function of the spinal cord. Such a diminution takes place only when one gives large doses, dangerous to life. Then the reflex function of the spinal cord ceases at the same time as all other functions.

It seems to be an accepted fact that quinine is less injurious to children than to adults, of course, taking into consideration that the doses for children are altogether smaller than those for adults.

Quinine has often been employed externally on account of its powerful antiseptic action, without showing injurious effects, when applied in the form of preparations with neutral or weakly alkaline reaction. Repeated frictions of ointment of quinine into the healthy skin cause abrasion and soreness.

TREATMENT.—The treatment of quinine-poisoning will vary with the various possibilities which

have just been described. Should a large dose of quinine be still in the stomach, sickness must be induced by mechanical irritation of the pharynx, or the stomach should be cleared by the pump. Nothing is more unwise than to try to empty the stomach by chemical emetics, such as tartar emetic or ipecacuanha. Firstly, much time is wasted by their application; and secondly—what is still more serious—if they really do act at last, they depress the nervous system and the heart, and diminish the power of resistance to the poison. If any emetic seems to be indicated, only a cautious hypodermic injection of hydrochloride of apomorphine can be permitted. Tannic acid or carbonate of sodium should be introduced into the stomach before or during evacuation, as quinine-salts are precipitated by these bodies in a much less soluble form.

In cases of *acute* quinine-poisoning recourse must be had to artificial respiration, with rhythmical pressure on the heart about thirty times a minute, as it produces strong mechanical irritation of this organ. Further, hot baths (40° C. or 104° F.), with cold affusions in a thin stream over the neck, should be tried. The room and bed in which the patient is lying must be kept as warm as possible. Strong hot coffee or tea is to be administered.

Stimulation of the kidneys is also required, to promote excretion of the alkaloid. Abundance of water containing free carbonic acid, like Seltzer or Apollinaris, mixed with small quantities of wine or other good alcoholic beverage, will answer this indication best.

As the head in such cases is of sufficiently low temperature, in consequence of the general depression of the body-heat, cold compresses to the head are not advisable. This part of the body must be kept low, in order to allow the weak action of the heart to maintain the cerebral circulation as easily as possible.

Most of the other symptoms caused by quinine disappear of themselves as soon as the drug is discontinued.

CARL BINZ.

QUINSY (*cynanche*, sore-throat).—A popular synonym for acute inflammation of the tonsils. See TONSILS, Diseases of.

QUINTAN (*quintus*, the fifth).—A form of ague, in which the paroxysm returns after an intermission of ninety-six hours. See MALARIAL DISEASE.

QUOTIDIAN (*quotidie*, daily).—A form of ague, in which the paroxysm occurs at the same hour every day. See MALARIAL DISEASE.

R

RABBI, in the Austrian Tyrol.—Chalybeate Waters. See MINERAL WATERS.

RABIES.—**DEFINITION.**—An acute disease, especially prevalent among the carnivora and dependent on the presence of a specific poison, chiefly in the nervous system.

ÆTIOLOGY.—The disease never arises spontaneously and is usually transmitted by bites. It is

possible that the virus present in the saliva of affected animals may occasionally infect others owing to the existence of abrasions, without actual biting. Isolated sporadic cases occur in all countries of Europe, and, from time to time, epidemics varying in severity. It is very usual for the malady to remain lurking in certain districts or countries. Thus foci of rabies are common in certain parts of Russia and of France, but rarer in central Europe.

In Great Britain more or less extensive epidemics of rabies have occurred from time to time. Since 1897, owing to the Muzzling Order, the disease has greatly diminished. During 1899 no human being died of hydrophobia in England or Wales, a result which had not been obtained during the last fifty-one years. In the year 1900 eleven cases were reported; this outbreak of rabies was confined to a district in the South-west of Wales. Rabies is, however, more frequent in Ireland. The disease is usually communicated by a rabid animal wandering at large, often over great distances, and biting other animals such as dogs, cats, horses, cattle.

The virus of rabies is especially abundant in the saliva and in the nervous system—both central and peripheral. There is some discrepancy among observers as to whether the virus is present before the symptoms of the malady are well established. According to Nocard and Roux the saliva of the dog may be virulent three days before the onset of symptoms; according to others, e.g. Dowdeswell, the central nervous system is not virulent until the animal shows symptoms of the malady. All parts of the nervous system are virulent at the time of death, but in the earlier stages of the malady both bulb and cerebro-spinal fluid are virulent. The blood, the lymph, the muscles, the liver, the spleen, and such secretions as the urine and the seminal fluid are usually stated not to contain the virus. On the other hand, such glands as the salivary, the lachrymal, and the pancreas contain the virus, and it has also been found occasionally in the milk.

All domestic mammalia are susceptible to rabies, although, from the habits of the animals, the disease is most likely to occur in dogs and cats. Birds are more refractory than mammals, especially to bites, but they can contract the disease through inoculation. Rabies is not rare in the wolf, the fox, and the deer.

Sub-dural inoculation is the most certain method of transmitting the disease experimentally, and next to this, inoculation into the aqueous humour; injection of the virus subcutaneously is a very uncertain method; it is more certain when injected deeply into muscles. Absorption from the gastro-intestinal tract has given different results, and in many cases the feeding of animals on the carcasses of animals dead of rabies has failed to transmit the disease. In other cases this method has succeeded, the explanation being doubtless that in some cases abrasions existed in the mucous membrane of the mouth and throat. The injection of the diluted virus prepared from the bulb into the veins is stated to confer immunity in the inoculated animal in the case of the horse, but in dogs and rabbits this is not the case; no immunity is produced and rabies may ensue. Drying destroys the activity of the virus in fourteen or fifteen days. If the spinal cord, however, be kept moist the virulence will persist for as long as forty days. Heating to a temperature of 48° C. destroys the virus in from five to ten minutes. Sunlight is said to destroy the virus in as short a time as fourteen hours. Putrefaction has an uncertain effect. In many cases the activity of the virus is not destroyed even after as long a period as forty days, but in other cases it may be destroyed earlier. Antiseptics such as perchloride of mercury in the strength of 1 in 1000 destroy the virus in a few minutes, and a 5-per-cent. solution of carbolic acid in approximately one hour.

INCUBATION.—The period of incubation is not only different in different animals but is liable to

somewhat considerable variations in the same animal. It is rather more variable after the transmission of the malady in the usual manner by a bite than when it is communicated by experimental inoculation. In most domestic animals the incubation-period varies from fifteen to sixty days. In dogs, according to Nocard, the disease in more than half the cases declares itself in less than one month after the bite, and in four-fifths of the cases the incubation-period is not more than sixty days.

After the passage of the virus through a considerable number of rabbits the incubation-period is shortened to six or seven days. This exaltation of the activity of the virus is not usually seen with less than 100 successive transmissions. Subsequently to this the activity of the virus becomes constant, the incubation-period being constantly six to seven days. This is spoken of as *le virus fixé* and is used in the Pasteur-method of prophylaxis.

SYMPTOMS.—Two forms of the malady exist, the *furiosus* and the *dumb*. In many animals, e.g. carnivora, one may precede the other, inasmuch as the later stages of the malady beginning as 'furiosus rabies' are characterised by symptoms similar to those seen in the 'dumb' form of the disease. In other animals, especially rabbits, the 'furiosus' form is rare, 'paralytic' or 'dumb' rabies being the usual type. 'Furious' rabies, however, may occur in rabbits as a result of inoculation or spontaneously, and 'dumb' rabies is not very uncommon in the carnivora. In both forms of rabies prodromal or premonitory symptoms are liable to be present. The prodromal period in dogs is characterised principally by an alteration in the habits of the animal. Quiet and friendly dogs become ill-tempered and restless, and are liable to conceal themselves in dark places. During this stage of the malady the animal may still be docile, and does not try to bite, and the appetite is maintained or may be increased. Irritation at the seat of the bite may be present, and very soon hallucinations develop, and the dog tries to avoid imaginary objects and may even snap in the air at them. This prodromal period passes insensibly into the second or fully established stage of the malady, in which the restlessness is greatly increased, and the dog suffers from paroxysms of violent excitement followed by remissions of exhaustion. In the paroxysms of excitement he destroys all objects that he encounters, and will, at this period of the malady, swallow a great variety of foreign bodies, such as sticks, straw, stones, rags, excrement, &c.

During this period the voice becomes altered so that the bark becomes extraordinarily high-pitched and has a peculiar falsetto quality. The peculiar nature of the bark is one of the characteristic features of the disease in its 'furiosus' form, and there is often a tendency for the animal to lie quietly for a time and then to suddenly jump up and utter the peculiar bark. The cause of the peculiar long-drawn bark is in part a paresis of the vocal cords.

When the dog is suffering from the fully established disease it is not uncommon for it to wander long distances, snapping and biting at objects, animals, and persons on its way. It is in this manner that a single rabid dog may communicate the disease to large numbers of other animals and also to man.

The paroxysms of furious excitement tend to become more and more marked for a time, but as

the disease progresses the periods of exhaustion between the paroxysms become longer; and, finally, during the last days of life, paralysis is fully established, and the animal is not only unable to swallow or to stand, but the jaw drops and the mouth gapes, with considerable quantities of stringy saliva hanging from it.

In 'dumb' or 'paralytic' rabies the onset of the malady is marked by somewhat similar sensory symptoms to those seen in the 'furious' form. After a short period, in which anxiety and agitation are the most marked features, the palsy sets in, in the form of paralysis of the muscles of the lower jaw, so that the mouth gapes owing to the dropping of the jaw. Although the dropping of the jaw is the most characteristic form of the palsy, this may assume other types, such as paraplegia, hemiplegia, or even monoplegia. The palsy that begins in the muscles of the jaw rapidly spreads to the muscles of the rest of the body, involving ultimately the muscles of respiration, and so causing death. 'Dumb' rabies is necessarily not so dangerous a malady as the 'furious' form, but although the animal is unable to bite, the disease may be communicated to others by careless handling of the dog; and in this way scratches about the hands may become infected from the saliva hanging round the mouth and teeth.

The average duration of 'furious' rabies in the dog is from four to five days, with a minimum of two and a maximum of ten. In 'dumb' rabies the average duration is from two to three days.

Glycosuria is not uncommonly present both in 'furious' and in 'dumb' rabies, and the urine may be examined for sugar after the death of an animal with suspicious symptoms. Glycosuria may be due to other causes, and its occurrence in rabies is more of interest than of importance.

Rabies runs a very similar course in both cat and dog. The 'furious' form is exceedingly well marked in the cat, and these animals are especially dangerous owing to their tendency to fly at and bite exposed parts of the body, such as the face.

In the horse the 'furious' form is also very well marked, and the animal becomes very savage, but the essential features of the malady are much the same as in the dog, and the average duration of the disease is from three to six days.

In the herbivora the average duration is from four to six days. During the height of the disease cattle will attempt to bite other animals or even man. Rabies in rabbits is usually of the 'dumb' or 'paralytic' variety.

MORBID ANATOMY.—The anatomical changes found in rabies are not well marked, and in many cases no changes at all are found owing to the animal having been killed at an early stage of the malady before the disease has existed a sufficient length of time to produce marked anatomical changes. The mucous membrane of the mouth, fauces, tongue, pharynx, stomach and intestine is usually congested and may present hæmorrhagic erosions or even ulcers. The tongue is often swollen, of a dark red colour, and the mouth generally injected, considerable quantities of ropy saliva hanging about the jaws. The stomach and intestines usually contain no food, but in the former is found a great variety of foreign bodies, such as hair, wood, straw, coals, hay, &c. The blood is often dark-coloured, the spleen congested, and the lungs gorged with blood with minute petechial

hæmorrhages on the surface of the serous membranes. The last, however, are only the results of death from asphyxia, and are of no great value as diagnostic signs of rabies. It is most essential to remember that rabies can never be excluded by *post-mortem* examination because the animal may have been killed, as is often the case, owing to a mere suspicion of the existence of the disease at such an early stage that none of the *post-mortem* phenomena are present.

Babes considers that the malady may be diagnosed with certainty owing to the presence of hyaline thickening and thrombi in the vessels of the central nervous system, especially the medulla. Van Gehuchten has described changes in the ganglia of the vagus, an acute degeneration of the nerve-cells of this ganglion, and he considers that by this means the disease can be diagnosed with certainty.

DIAGNOSIS.—In the 'furious' form of the disease the most characteristic clinical feature is unquestionably the bark. All dogs in which the malady is suspected should be isolated, because it is difficult, if not impossible, by a single examination in the early stages of the disease to determine with certainty the nature of the malady. Its clinical course is so rapid and characteristic that a few days' isolation will generally determine the question with certainty.

The following diseases are liable to be confounded with rabies: Epilepsy and diseases of the external auditory meatus, cysticercus in the brain, distemper, gastritis and enteritis, and in a few instances tetanus. Foreign bodies in the fauces and inflammation of the temporo-maxillary articulation, from rheumatic or other causes, are the diseases most apt to be confounded with 'dumb' rabies.

The *post-mortem* diagnosis is very unreliable for the reasons already mentioned. The most characteristic phenomena are the absence of food in the alimentary canal together with the presence of foreign bodies and hæmorrhages in the stomach. Some writers lay great stress on the presence of sugar in the urine.

EXPERIMENTAL DIAGNOSIS.—The only method of determining with certainty the presence of rabies after death is by the inoculation of a portion of the brain or spinal cord from the suspected animal subdurally in the rabbit. A portion of the central nervous system, preferably the bulb, of the suspected case of rabies should be placed in glycerine for three days; an emulsion of the brain should then be prepared with sterilised salt-solution and a few drops injected subdurally in the rabbit, subdural inoculation being more certain than that into the aqueous humour of the eye. After an incubation-period of from fourteen to nineteen days, but sometimes amounting to as much as six weeks, the paralytic form of the disease manifests itself in the rabbit, and owing to its typical features and characteristic course can be readily diagnosed. In a few instances the experimental method will fail owing to the contamination of the suspected brain with some septicæmic virus, the rabbit dying from the septicæmic infection at a period so early that the rabies cannot be manifested. The experimental method can be used even when the cord and brain are in a state of putrefaction; in a considerable number of cases injection of the decomposed or even putrid brain beneath the dura mater is not only not followed by any immediate serious consequences, but the virus of rabies if present may

still be able to manifest its presence in the usual way. A negative result after the sub-dural injection of decomposed brain-tissue suspected of containing the virus of rabies is of little value, as putrefaction unquestionably may destroy the virus. The great disadvantage of the experimental method of diagnosis is the fact that on an average some three weeks are necessary in order to determine with certainty the presence or absence of rabies.

TREATMENT.—Rabies is such a serious disease in animals, and the danger of the communication of hydrophobia to man is so great, that it is not customary to attempt to treat the malady. Animals undoubtedly suffering from the malady should be killed, and it is usually recommended to burn their carcasses. An animal bitten by another suffering from rabies may be treated on the same lines as the Pasteur treatment of hydrophobia, but the disease is such a terrible one that it is better to immediately kill all animals that have been bitten by an animal suspected of rabies. If an animal suspected of rabies has bitten any human being, it should be isolated and not destroyed until it has been determined whether the animal is rabid or not. When destroyed this opinion should be confirmed by experimental inoculation. If an animal has been in company with one affected with rabies it should be isolated and, according to some writers, the period of isolation should be at least four months. All kennels, dog-collars, &c., which have been used by a rabid animal should be disinfected with a powerful antiseptic such as perchloride of mercury.

Rabies can be checked, and in many cases entirely prevented, by the systematic and thorough muzzling of dogs, and by regulations directed to prevent the importation of animals, especially dogs, from countries where rabies is prevalent. It is to the thorough carrying out of the Muzzling Order that the extinction of the last epidemic in this country is due. In addition to this it would be very advisable that dog-owners should be compelled to have collars with their name and address on their dogs.

RAILWAY INJURIES.—**DESCRIPTION.**—The points of difference between railway injuries and those sustained in other ways, such, for instance, as by a fall from a horse or a carriage, are virtually those of degree. The more serious results are referable, firstly, to the great weight and impulse of the railway train, crushing, perhaps completely, some portion of the body; secondly, in the case of collision, to the sudden arrest of momentum of such ponderous bodies in more or less rapid motion, causing thereby violent vibratory shocks to the travellers; and, thirdly, the occurrence being sudden and unexpected, the muscles are, as it were, taken by surprise, and before contraction can take place the ligaments of the spine are frequently strained or even torn, while in other cases unequal and unbalanced muscular spasm leads to serious lesions. There is no time for preparation; the whole is the work of an instant. In cases of injury

to those who jump or fall from a train in motion, the gravity of the resulting injury depends on the rate of speed of the train at the moment; on the part of the body which first strikes the ground, and the angle at which it is struck; on the weight of the individual; and also on the nature of the ground.

Accidents which happen to persons either getting into or out of trains not in motion, possess no unusual characters. Serious spinal injuries have, however, occurred to those sitting in a train not in motion, when, by a sudden unexpected jerk, as from a train running into it from behind, a violent shock is sustained.

It is, then, the sudden and violent character of the occurrence, the alarm and fright necessarily associated therewith, the general jar or commotion of the nervous system, and possibly the localised physical damage, which constitute the main features of this class of injuries, conditions which do not obtain in cases of less sudden violence.

RESULTS.—1. The *direct* or *immediate* results of railway accidents are of various kinds. Locally, they consist of simple or compound fractures, contusions, and lacerations, caused either by the force of the collision, by the limbs being caught between the seats of the carriage, by the wheels of the carriages where the individual has been run over, or by fragments of splintered wood, iron, or glass. Burns and scalds may add to the sufferings of the injured. These injuries, if not resulting immediately in death, may ultimately prove fatal in various ways, or permanent injury to a greater or less extent may ensue. Such conditions, however, are not peculiar to railway injuries, and need no special description here.

The immediate effects on the cerebro-spinal system are, on the other hand, of special interest and importance. Local injuries, even fractures of the spinal column or head, are frequently met with, while in other instances serious lesions, accompanied by hæmorrhages, occur in the brain or spinal cord or their membranes, without any fracture; but *ligamentous* lesions of the spine are perhaps the most characteristic features of railway injuries. Death has resulted from sheer fright, especially in persons suffering from heart-disease, aneurysm, and the like. The primary depression produced on the nervous and circulatory systems continues and deepens, there is no power to rally, and a fatal result from syncope ensues. General shock or concussion is also commonly met with, where the symptoms are mainly subjective; and in emotional individuals an attack of acute hysteria may be induced, laying the foundation of a chronic condition.

For a description of concussion of the cord, and of the localisation of lesions of the cord, see SPINAL CORD, Diseases of.

2. The *indirect* or *remote* results of railway injuries are numerous and varied in character. *Locally*, it must not be forgotten that an accident may readily light up chronic inflammatory mischief in individuals who are predisposed by some inherited or acquired weakness, or by some particular diathesis. Thus syphilitic, tubercular, gouty, and even cancerous disease may follow and complicate the symptoms arising from the injury. Again, chronic inflammatory conditions of the spinal cord and its membranes may be induced thereby, and the usual train of symptoms accompanying such lesions will be manifested. But, apart from the existence

of such organic mischief, certain indefinite phenomena, subjective and functional in character, are constantly met with, which render the diagnosis and prognosis of railway injuries difficult, and considerably increase the responsibilities of the medical attendants. It is especially, however, when there is no local lesion of importance, such as a fractured limb, that these general 'neurasthenic' conditions are likely to occur; for it can be readily understood that if the force of the accident expend itself upon some injury, say, to one of the extremities, there is less likelihood of a general concussion of the nervous system. The familiar and often-quoted illustration is that of a watch, in which the works are less likely to be damaged by a fall if part of the violence be expended in breaking the glass. This neurasthenic condition is evidently the expression of an exhausted nervous system, and may come on in various ways and at various times after the accident. The mental shock is to be held responsible for its occurrence nearly as much as is the physical. It may arise out of the general collapse or shock into which the patient has been suddenly thrown by the accident, but perhaps more commonly the extent of the mischief is not evident at the time. As a typical illustration of such a case, the following may be taken: A person in a collision receives a sudden, unexpected, and violent shock, the result of being thrown or jolted backwards and forwards. He feels faint and collapsed for a few moments, but recovers sufficiently to be able to assist his fellow sufferers; returns home, and resumes his usual avocations. After an interval of a few hours or days he begins to complain of pain and stiffness in the back and neck, but particularly in the lumbo-dorsal region. He goes to his business, but cannot attend to it, being unable to concentrate his attention or make calculations, any special effort resulting in marked headache. He is unable to read comfortably, as the letters run into one another and become blurred. He goes home and consults his medical man, who probably advises rest in bed, and prescribes bromide of potassium, &c. The temperature in these cases is often sub-normal, and the pulse sometimes rapid, sometimes slow. These symptoms in the majority of cases pass away after a short rest, and terminate in complete recovery. In other cases, fortunately the exceptions, further symptoms develop, such as irritability of the bladder, inability to empty the viscus, occasional dribbling of urine, lightning pains in the spine, spasm of the legs, and others too numerous to mention here. These may depend either upon the condition of neurasthenia, just alluded to; or more rarely upon definite congestive or other pathological changes occurring in the spinal cord. The prognosis of the latter is grave in the extreme.

In the condition of neurasthenia, asthenopia, with difficulty in or real loss of the power of accommodation, may be one of the causes of the impaired vision just mentioned. Physical changes in the retina and optic disc are extremely uncommon. In all probability, they only exist as sequelae of organic lesions of the spinal cord and membranes.

Added to this neurasthenic condition, there is often seen a certain amount of functional disturbance, probably of cerebral (cortical) origin, which may be described as chronic hysteria, under which one includes changes of various kinds in the cutaneous sensibility, spasmodic contractions of limbs, and paralyses; and it is often a most difficult ques-

tion to decide whether these phenomena are functional or organic. Cases such as these are frequently the subject of litigation as regards claims for damages against railway companies.

MEDICO-LEGAL QUESTIONS IN CONNECTION WITH RAILWAY ACCIDENTS.—In cases of claim for compensation for these injuries, it is of the highest importance that the medical men engaged should make themselves thoroughly acquainted with all the circumstances connected with the accident and its results. This applies to the *medical attendant* of the injured person, as well as to the *medical officer* examining on behalf of the company.

Duties of the Medical Attendant.—1. It is desirable to obtain in writing the *patient's statement* as regards: (a) the accident; ascertaining, if possible, the approximate speed of the train when the accident occurred, the position of the injured person in the carriage, and of the carriage in the train; also whether other persons were present or not; (b) his condition from the time of the accident to the time of his examination; and (c) the symptoms complained of at the time of his examination.

2. Investigate the general condition of the patient, especially as to his appetite, and his capacity for sleep or work; ascertain also his previous habits. The possible existence of organic disease, previous to the accident, should not be overlooked, as it has happened that symptoms referable to disease—tabes dorsalis, for example—have been erroneously ascribed to injury. The urine should be carefully examined in every case.

3. Note bruises or any sign of local injury on any part of the body.

4. Where injury to the spine is alleged, the investigation should be conducted as far as possible according to the following systematic plan:—

(i.) Notice the amount of mobility or rigidity of the spine while the patient is undressing.

(ii.) Examine the spine by digital pressure or percussion, and by the application of hot or cold sponges.

(iii.) Investigate any alleged paralytic symptoms by (a) measuring the circumference of the limbs, where needful; the right side, it should be remembered, is usually somewhat fuller than the left, and the existence of any other pre-existing inequality of the limbs should not be lost sight of; (b) testing the electrical excitability of the muscles; (c) noting the existence of spasm or tremor of the muscles of the spine and limbs; and (d) examining the condition of the reflexes, superficial and deep.

5. Investigate the presence of any abnormal cutaneous sensibility. This is entirely a subjective phenomenon, on which reliance cannot always be placed.

6. Ophthalmoscopic examination may be necessary in order to determine the existence or not of local lesion in the fundus oculi, confirmatory or otherwise of cerebral or spinal symptoms; but, as already stated, such pathological changes are exceedingly rare.

During this examination, it should be borne in mind that the simulation of symptoms, such as spinal tenderness or muscular tremor, can frequently be detected by distracting the attention, when pressure on the part previously complained of may be made with impunity, or the muscular tremors will cease. This, however, is not conclusive of inten-

ional imposture, for in hysteria, when the attention is diverted, the same occurs.

As an instance where the truth of a patient's statements may be tested by the astuteness of the medical man, a case may be mentioned in which the plaintiff, who had travelled up some fifty miles to London to be examined, stated, among other symptoms, that his urine continually dribbled from him. The surgeon immediately asked to see his shirt, which had been worn at least six hours, when it was found perfectly dry and devoid of any stain of urine! In another case a man complained of extreme spinal tenderness, even when the part was merely blown upon. A sheet of paper being interposed, without the patient's knowledge, the effect was the same!

It now becomes the duty of the medical attendant to form an opinion on the following points:—

- (a) Has the patient been really injured?
- (b) What is the nature of the injury?
- (c) Is the injury a possible or probable result of the accident as described?
- (d) Are the symptoms consistent with the history and the objective signs?

Duties of the Medical Officer examining on behalf of the Railway Company.—The medical officer of the company should on no account constitute himself the agent of the company for settling the terms of compensation. The examination should be made, if possible, in the presence of the medical attendant of the patient, and not in the presence of the legal advisers of either side; it should be conducted with thoroughness and tact, and without inflicting any unnecessary pain.

A report of the case should be drawn up from notes taken at the time, giving:—

- (1) The patient's account of the accident, and of his subsequent and present symptoms.
- (2) The present condition of the patient, noting particularly any *objective* signs of injury.
- (3) An opinion as to whether the symptoms complained of are likely to be the result of the accident; and as to the probability of recovery, and at what period.

As the plaintiff's solicitors in an action can apply for a copy of this report, it should, of course, be worded with extreme care.

The actual question of pecuniary compensation does not concern either the medical attendant of the patient, or the medical adviser of the company. They merely have respectively to bring forward facts in support of their opinions as to the value of symptoms, and how far they are dependent upon the injury.

Such investigation should take place as soon after the accident as possible, by which means the chances of imposture would be lessened; while by a careful and impartial estimate of the facts of the case as obtained by such a thorough examination as that sketched above, much conflict of medical opinion would be avoided, the medical men being witnesses, not advocates.

At the above examination the question of the future treatment of the plaintiff may be raised by his doctor, but the medical officer of the company should be extremely cautious in giving advice or making suggestions.

Fraudulent Claims.—It will be well to allude to some of the ways in which fraudulent claims are brought against railway companies. These may be conveniently divided into:—

(1) Claims made by persons who, as may be subsequently proved, were not even in the train.

(2) Claims by those who, though present and unhurt, yet simulate the symptoms of injury; and

(3) Claims by those who, having sustained some trifling injury, wilfully and intentionally exaggerate their symptoms in order to obtain a larger amount in compensation.

The medical man should, therefore, be alive to the possibility of wilful deception being practised on him, lest he should be led away by a well-planned history, and thus unwittingly be made a party to such fraudulent transactions.

Unintentional Exaggeration.—The difficulty of assessing the value of subjective symptoms in general is much increased by the fact that there are certain persons who, undoubtedly injured, may, without any fraudulent design, unintentionally exaggerate their symptoms. This is to some extent explained by their thoughts being constantly directed to their sufferings, and the worry necessarily attending a protracted lawsuit, or while an action for damages is pending. The suspense and anxiety, the examinations by the medical men, and the repeated interviews with their solicitors, keep them in a constant state of nervous tension. When, therefore, their claims are settled, it is natural that the relief they experience should frequently be attended by beneficial results, or even complete recovery. See **FEIGNED DISEASES**.

TREATMENT.—The chief injuries received at the time of a railway accident being surgical, the treatment adapted for each particular case will be found in surgical works. Nevertheless there are some general points in the immediate treatment to which any medical man present on such occasions would do well to attend.

In the present day, thanks to the efficient training given on most railways to the guards and other employés in ambulance work, the administration of first aid is more intelligently carried out, and has frequently been the means of saving life.

1. *Hæmorrhage.*—Death from hæmorrhage should be prevented, where possible, by promptly adopting pressure of some kind. If no tourniquet or india-rubber band be available, a handkerchief tied round the limb and twisted tight with a piece of stick, or direct pressure by the finger, will suffice for the time.

2. *Fractures.*—Temporary splints may be improvised out of umbrellas, walking-sticks, cushions, newspapers, and broken pieces of wood, &c., fixed by straps or handkerchiefs, so that the injured may be removed with as little pain as possible, and simple fractures may be prevented from becoming compound. Simple dislocations should be reduced at once, if possible.

3. *Shock, collapse, and fright.*—In the treatment of these conditions great caution is required to maintain the vital powers until reaction sets in. The temperature of the body, the strength and rate of the heart's action, together with the respiration, should be kept up by stimulants and warmth. There is, however, a danger of *over-stimulation*, whereby the flickering powers of nature may be extinguished altogether.

4. *Exposure to wet and cold.*—Every endeavour should of course be made to prevent prolonged exposure, by sheltering the injured as much as possible, and securing their early removal to any neighbouring houses. This question of moving the

injured passengers, many of whom may be suffering from profound shock, is often a difficult one to decide. On the one hand the local means of treatment may be very limited, while, on the other, a long journey may be before the patient, and the means of transport are often inadequate in consequence of the construction of the rolling stock, whereby it is extremely difficult to transfer a recumbent passenger through the narrow doorways. It has been suggested either that every train should have a coach attached to it capable of being used as an ambulance van, or that at the principal stations fully equipped hospital vans should be kept in readiness to be attached to the break-down relief train.

The subsequent treatment of railway injuries is one which requires the exercise of considerable skill and judgment on the part of the medical attendant. Absolute rest is of course a *sine quâ non* where any spinal concussion or local lesion is suspected; but where the symptoms are due to neurasthenia, long confinement in the horizontal position is often productive of harm, whereas change of scene and moderate exercise might prove beneficial.

RAPE.—SYNON.: Fr. *Viol*; Ger. *Nothzucht*.

DEFINITION.—By the English law rape is defined as ‘the carnal knowledge of a woman forcibly and against her will.’

GENERAL REMARKS.—The crime of rape is punishable by penal servitude for life. By the Criminal Law Amendment Act of 1885 the defilement of a girl under thirteen is a felony punishable by penal servitude for life, and the attempt to have carnal knowledge of a girl under thirteen is a misdemeanour punishable by two years’ hard labour, or by a whipping if the offender be under sixteen. The carnal knowledge of a girl between thirteen and sixteen, or the carnal knowledge of an idiot or imbecile girl, is a misdemeanour punishable by two years’ hard labour.

Of cases of rape recorded by Casper, 73 per cent. were upon the persons of little children under twelve. Of 136 cases put upon record by this author, the ages were as follows:—

From	2½	to 12 years of age,	99 cases
„	12	„ 14	„ 20
„	15	„ 18	„ 8
„	19	„ 25	„ 7
		47	„ 1 case
		68	„ 1

For proof of the crime of rape it is not necessary that the force employed should have been of a violent physical kind. A mere *threat* of violence, or even of moral injury, is ‘force’ in the eyes of the law. The surreptitious administration of chloroform, or a narcotic, for the purpose of having intercourse with a woman against her will, is also force in the eyes of the law. The Criminal Law Amendment Act quoted above has the following clause: ‘Whereas doubts have been entertained whether a

man who induces a married woman to permit him to have connection with her by personating her husband is or is not guilty of rape, it is hereby enacted and declared that every such offender shall be deemed to be guilty of rape.’

The moral character of the woman is theoretically, but seldom practically, beside the question; and, provided force be used, and the woman’s consent be wanting, sexual intercourse even with a prostitute is legally ‘rape.’

The punishment of the crime of rape was provided for in the criminal code of Moses, who ordained that the ravisher of a betrothed damsel should die.

The Roman law punished the crime with death and confiscation of goods, but provided the following saving clause:—

Rapta raptoris, aut mortem, aut indotatas nuptias optet.

Upon this, says Percival, there arose what was thought a doubtful case: ‘*Una nocte quidam duas rapuit; altera mortem optat, altera nuptias.*’

Many accusations of rape are false and trumped up, and are only brought by the woman when she finds that some sexual indiscretion is likely to bring her into trouble, or cannot be concealed by reason of her pregnancy.

This being the case, *stale accusations* should be received with very great caution. The laws of Henry III. provided that the accusation should be made immediately ‘*dum recens fuerit maleficium.*’ By the old Scotch law no delay was allowed in bringing the accusation *ultra unam noctem*, and by the modern Scotch law a delay of three days is alone permitted. By the law of England no limit is placed on the time at which an accusation of rape may be made. An English jury is, however, naturally chary of giving credence to a stale charge of rape. Some few years back a charge of rape was brought against a gentleman of position in one of the home counties by a girl with whom he had had connection some five months previously. There was no evidence that the girl had offered any resistance, and as the accusation was brought only after pregnancy had become evident, and after ineffectual attempts had been made to extort money from the defendant’s relatives, and as the charge was evidently made at the instigation of an uncle who was a superintendent of police, and a cousin who was a lawyer, the case was dismissed. It shows, we think, an imperfection in the English law that it should be possible, under such circumstances, to prefer a charge of so serious a crime.

The law for the substantiation of a charge of rape is satisfied with proof of a minimum amount of ‘carnal knowledge.’ The mere touching of the vulva by the penis is carnal knowledge in the eyes of the law. The complete introduction of the penis into the vagina need not be proved, and still more is proof of emission unnecessary.

THE SIGNS OF RAPE.—From what has gone before, it is evident that there need be no signs whatever. If a girl be overawed by a threat and her vulva be touched by the penis, that is rape; and, if proved, is punishable as such.

On the other hand, the evidence of rape may be very convincing; for example:—

(a) The woman may have been heard to cry for help.

(b) There may be the signs of a struggle at the spot where the rape was alleged to have occurred.

(c) There may be damage to the woman's clothing, and bruises of various parts of her body—signs that she has been subjected to physical force.

(d) The genital organs may be found injured; the vulva bruised and perhaps bleeding; the hymen recently ruptured; and, in cases where the disparity in size between the man and woman is very great, rupture of the perineum and mortal injuries to the vagina.

(e) Seminal spots may be found upon the woman's clothing, which is a certain proof of a previous intimate relation with a male. Blood-spots also afford valuable evidence, but necessarily not so conclusive. Care must be taken not to confound menstrual fluid with blood.

The concurrence of all these signs would amount to certain evidence of forcible connection. It must be borne in mind, however, that violence may be done to the female organs in other ways than by forcible connection, and the medical examiner should be upon his guard against inferring too much from the evidence afforded. He also should be on the look-out for facts which may rebut assertions made by the woman. Thus, signs of a previous pregnancy or the evidence of previous venereal disease (scars in the groin, sores upon the pudenda, or symptoms of constitutional syphilis) may serve to disprove any assertions which might be made as to the woman's virginity or previous chastity. To *prove* whether or no a woman be *virgo intacta* is next to impossible, and we can only state the probabilities for and against. Such a question, however, is quite beside the mark in many cases of rape; but the presence of an unruptured hymen is an unlikely occurrence after forcible connection. An examination of the person of the supposed ravisher may afford some corroborative evidence. Blood or recent seminal spots upon the linen or clothing, and injury to the person or clothing, all afford their quota of evidence of a sexual act combined with violence.

It is a matter of doubt whether the rape of a woman of fair size and strength be possible by an unaided man. If a woman be in the enjoyment of her faculties she is capable of offering an amount of resistance which would be well-nigh insuperable; and if she have offered a decent resistance, the person of the ravisher should bear evidence of it.

Rape, as we have seen, is most often committed on children of tender years. It is well to be on one's guard against error with regard to the rape of little children. It must have come within the experience of most members of the profession, and especially of those engaged in hospital practice, to have brought to them children suffering from a purulent discharge from the vagina, the mother at the same time alleging that some one must have violated the child. It must be borne in mind that purulent discharges from the vagina are not uncommon in ill-fed, dirty, scrofulous children; and that after some of the infantile acute specific, sloughing of the pudenda is a rare, though recognised occurrence. The case of Jane Hampson, *et. 4*, who died of sloughing of the genitals at Manchester in 1791, should stand as an incentive to caution in these matters. The signs were considered as those of defloration, and the coroner's jury returned a verdict of *murder* against the boy who slept with her; but luckily for the male child there occurred many other cases of sloughing of the pudenda in Manchester before he was brought to

trial, and as the doctor who was called to Hampson recognised and acknowledged his error, the boy was discharged. It was at one time a popular belief that connection with a virgin was a sure cure for venereal disease, and this has led, no doubt, to many cases of rape on young children. The presence of venereal disease in one or both of the parties may be of value as evidence. Its presence in the woman and not in the man affords a strong presumption against rape.

The finding of spermatozoa within the vagina is proof positive of connection. But here, again, care must be taken not to mistake for spermatozoa the *Trichomonas vaginalis*—a microscopic organism, not unlike a tadpole in shape, which has been described by Donné as occasionally found in vaginal mucus. It must be remembered, also, that seminal fluid may contain no spermatozoa. Rape is occasionally effected with so much violence that death results. Ogston records the case of one Margaret Paterson, who was raped between Edinburgh and Dalkeith by two carters, who took her into their cart on the pretence of helping her on her journey. They forcibly held her down and repeatedly violated her person, and afterwards took stones from the road, coals, straw, prickly plants, &c., and forced them into the vagina. They then left her in a ditch, and she died in three days of her injuries. *Post mortem* the vagina and rectum were found lacerated and broken down into one passage, and the abdominal viscera in a high state of inflammation. The two carters were convicted and executed. This case does not stand alone, for it is an interesting fact that rape has not infrequently been accompanied by acts of violence which are not only brutal and senseless, but which appear to have no relation to sexual acts or feelings.

It has been doubted whether pregnancy can follow rape, but there seems to be no sufficient grounds for this doubt.

DUTIES OF THE MEDICAL EXAMINER.—When called to a case of supposed rape, the medical examiner must remember to take note of every circumstance—the time that has elapsed since the alleged outrage, the mental state of the woman, her size and physical power as compared with that of the man, and evidences of a struggle in the surroundings of the woman, or on her clothing and person. He should keep his mind open to receive any facts which may throw light on the moral character of the woman. He should accurately take note of the exact condition of the genital organs and linen; should take possession of all stained linen for the purpose of chemical and microscopic examination; and should remove a portion of any discharge which may be found in the vagina for the same purpose. In drawing up a report, he should describe, as accurately and drily as possible, all facts which he may notice; and should be carefully upon his guard against drawing any undue conclusions from those facts.

G. V. POORE.

RASH.—An outbreak of redness of the skin, or efflorescence; called by the Greeks an *exanthema*, or blossoming out. The word conveys the idea of suddenness, while in reference to development it is generally extensive. The best illustrations of the rashes and of the meaning of the term are seen in erythema, roseola, rubeola, scarlatina, and urticaria.

RAYNAUD'S DISEASE. — **SYNON.** : Local Asphyxia and Symmetrical Gangrene of the Extremities ; Fr. *Asphyxie locale* ; *Gangrène Symétrique* ; Ger. *Symmetrische Gangrän*.

DEFINITION.—A disease characterised by disorders of the circulation in the peripheral parts, frequently symmetrical in distribution and depending on paroxysmal diminution or arrest of the flow of blood in the affected parts.

VARIETIES AND DESCRIPTION.—Under the name of Raynaud's disease there are included a number of vaso-motor phenomena which may conveniently be grouped into three main classes ; each of these may constitute the whole disease ; or two or more varieties may co-exist or replace one another. These three varieties are known as (1) Local syncope or regional ischæmia ; (2) Local asphyxia or local cyanosis or acro-asphyxia ; and (3) Local gangrene, symmetrical gangrene or acro-sphacelus.

(1) **Local Syncope.**—This variety chiefly affects the fingers, toes, hands, feet, and more rarely the ears, face or limbs.

An attack of local syncope usually commences with a sensation of numbness, tingling, or slight pain in the affected part. This latter becomes pale and cold, the skin having a waxy look, or being actually shrivelled. The part may become so bloodless that, when pricked or cut into, it does not bleed. The finer movements of the fingers are interfered with—writing, sewing and similar acts becoming difficult or impossible. Tactile sensation is blunted, but impressions of heat and cold are correctly interpreted. Commencing in one finger the condition may spread to other fingers on the same hand, or to the corresponding ones of the opposite hand, or it may remain localised to one finger all the time. The fingers are more frequently affected than the thumbs or the toes.

The attack lasts a time varying from a few minutes to several hours or even days, the part either gradually and insensibly returning to its previous condition, or this restoration being accompanied by a sensation of tingling or of burning pain, and occasionally by sweating of the part. After repeated or prolonged attacks the fingers become tapered at their tips.

An attack of local syncope may occur without any recognised cause, or may follow exposure to cold, such as from washing the hands in cold water ; exercise and mental excitement or emotion may also induce an attack. Attacks may recur from time to time from slight thermal or emotional changes, or may recur regularly in the absence of these in a manner strongly suggestive of some malarial influence.

The frequency of the attacks varies considerably, in some cases intervals of only an hour, in others of a week, being present.

During an attack very little change can be made out in the artery supplying the part, but changes characterised by the breaking up of the red blood-corpuscles have been noted in the blood of the ischæmic part.

The condition of local syncope may be followed by local asphyxia, or even by gangrene of small portions of the skin of the finger-tips.

2. **Local Asphyxia (Local Cyanosis).**—This variety is the one most commonly met with. It may succeed an attack of local syncope, or occur with only a passing pallor ushering it in. It is charac-

terised by the cyanotic appearance of the parts affected. These are most commonly the extremities—fingers, toes, hands, feet, ears, nose, cheeks, and occasionally portions of the trunk. The extent involved in local cyanosis is usually greater than in local syncope, but the distribution is less symmetrical. An attack usually commences with a transient pallor, followed by cyanosis of the part. The degree of cyanosis is inconstant, and gives rise to tints varying from a reddish-purple to a blue-black colour. The colour of the affected part is not uniform, and the same area may present varying shades of colour. Pressure over the cyanotic part is followed by a pallor which is only slowly replaced by the colour of the surrounding parts. The cyanotic portion is cold, swollen, and tender. In one of Raynaud's cases the surface-temperature of the affected hand was 27° F. below the temperature in the axilla. The swelling of the part is usually moderate, and there may be some pitting on pressure, but occasionally it is very marked. Subjective sensations of cold, tingling, pain or even agony are experienced, and pressure is ill-borne. As a rule, cold applications relieve, and hot ones intensify, the pain. Areas of anæsthesia are not uncommon. During the attack the artery supplying the part may be felt to be smaller and harder than the corresponding one on the opposite side, and Barlow has observed moniliform swellings on the veins of the affected part, which altered in position and which he ascribes to varying contractions of the walls of the veins. Sweating of the part is frequently observed during an attack, and the patient may shiver, vomit, and suffer from abdominal pain. The duration of an attack varies from minutes to months. The attack usually passes off slowly, livid spots making their appearance in the cyanotic area, and sometimes reddish-purple areas (*tachetées*) occur in the neighbourhood of the cyanotic region. The return to the normal may be accompanied by tingling sensations. Local cyanosis not infrequently passes on to local gangrene. The onset of an attack may be determined by the same factors which induce local syncope, and attacks are very prone to recur. The blood drawn from the site of local cyanosis is dark, and shows oligocythæmia and a breaking down of red corpuscles and some leucocytosis. Attacks of local cyanosis are sometimes followed, or accompanied, by hæmoglobinuria, sclerodermia, urticaria, fibrous ankylosis of the terminal phalanges, amblyopia, or iridoplegia.

3. **Local or Symmetrical Gangrene.**—This variety never occurs as a primary condition, but may follow either on repeated and prolonged attacks of local syncope, or, much more commonly, of local asphyxia. The parts most commonly affected are the toes, fingers, ears, cheeks, nose, and nates. The distribution of the gangrene is sometimes, but by no means frequently, symmetrical. One or more digits may be attacked. The onset of gangrene is usually signalled by the appearance of small blebs, situated usually on the plantar surface of the toes, or about the nail in the case of the fingers. These blebs give exit to some blood-stained, sterile serum, and leave a little black patch of epidermis, which is gradually shed by a process of ulceration. In more severe cases the true skin and the subcutaneous tissue are involved, and the bones may be laid bare. Occasionally the necrosis extends up the limbs, but as a rule it is confined to the extremities. Although the gangrenous part is neces-

arily insensible, yet the neighbouring parts are often exquisitely painful to the touch during the process of separation. The gangrene is always of the dry variety, i.e. is a process of mummification. Healing takes place slowly, but presents no peculiarities except that the gangrenous areas leave much less loss of tissue than would have been expected. In none of the three varieties of Raynaud's disease is there any marked pyrexia.

ÆTIOLOGY.—*Age.*—Raynaud's disease may occur at any age, but is most common between 20 and 40 years of age. Several cases are recorded in children under one year of age, and cases occurring in patients over 70 years of age are also known.

Sex.—Females are more liable than males. In 180 cases collected by Munro 62·6 per cent. were females, and 37·4 per cent. males; and of the cases admitted into the Middlesex Hospital during ten years, 74 per cent. were females, and 26 per cent. males.

Direct heredity was present in 8 per cent. of Munro's cases.

Relation to other Diseases.—Raynaud's disease has been met with in association with some of the acute specific fevers, such as typhoid fever, also with malaria, syphilis, neurasthenia, insanity, menstrual disorders, scleroderma, carcinoma of the stomach, and paroxysmal hæmoglobinuria. Although in several of Raynaud's cases malaria was present, it is to Mourson and Calmette that we are indebted for the observation of the relationship between the two conditions. Raynaud's disease seems common in some malarious districts, but in a large number of cases there is no history or evidence of malaria, and 8 per cent. is probably a high estimate of the number of cases in which malaria plays any part. Syphilis, either congenital or acquired, plays in relation to Raynaud's disease an interesting part, both from the fact that many cases of paroxysmal hæmoglobinuria occur in the subjects of syphilis, and also from the narrowing of the arteries, which may result from syphilitic arteritis. Of all the diseases with which Raynaud's disease is associated paroxysmal hæmoglobinuria is the most interesting, and the connection is so close that Abercrombie regards this condition as a symptom of Raynaud's disease. Most writers have noted the frequent concurrence of the two conditions, and, in several cases of paroxysmal hæmoglobinuria in children, have observed local syncope and local asphyxia of the hands and feet. The attacks of hæmoglobinuria do not always coincide with the local asphyxia or cyanosis. Paroxysmal hæmoglobinuria occurred in about 6 per cent. of the 180 cases collected by Munro. Scleroderma occurred in 7·2 per cent. of Munro's cases, but it has not been observed in association with hæmoglobinuria.

MORBID ANATOMY AND PATHOLOGY.—No constant change has been found either in the vascular or nervous system. The arteries have in several cases been found healthy; in other cases thickening of all three coats has been observed, and Barlow suggests that this may be the result of repeated spasmodic contractions of the vessel walls. Endarteritis has been observed in both syphilitic and non-syphilitic cases. In both the central and peripheral parts of the nervous system changes are inconstant. In a few cases, peripheral neuritis has been observed in the nerves of the affected part, but it is often difficult to distinguish the neuritis due to the gangrenous processes in a part from those which

may be primary and cause the necrosis. The blood in the affected part has been shown to undergo changes consisting in the breaking up of the red corpuscles and a slight leucocytosis.

The paroxysmal nature of the attacks—the return to normal conditions in the intervals, the absence of any degenerative changes in the vessels in most of the cases in young subjects, and the direct observation of the altered pulse in the part and of the changes in the veins, as well as the evidence of vascular spasm obtained by ophthalmoscopic examination made during an attack of local asphyxia, all point to the morbid condition being one of active spasm of the vessel-walls with diminution or arrest of the flow of blood through the affected vessels. The influence of cold or emotion in inducing an attack points to this condition of vascular spasm as being a reflex act, the vaso-motor centres being in an unduly irritable condition so that vascular spasm is readily induced and maintained. The symmetrical character of many of the attacks lends additional probability to the central nature of the change. Changes once initiated tend to recur with undue readiness, and thus we get from slight causes recurrent attacks of vaso-motor spasm.

The view that the disease is a primary peripheral neuritis is negated by the absence of evidence of such a condition in some of the cases examined.

The actual condition of local syncope is due to contraction of the arterioles and venules; while in local cyanosis there is also contraction of the veins. In local gangrene we have probably complete arrest of the circulation in the part and not the incidence of any special necrosing agents such as those derived from certain micro-organisms, for the serum from the blebs in the gangrenous patches has been shown to be sterile. By some local syncope and asphyxia are regarded as angio-neuroses, while symmetrical gangrene is regarded as an angio-trophoneurosis to which latter category scleroderma is also relegated.

DIAGNOSIS.—The diagnosis of a typical case of Raynaud's disease presents no difficulties, but cases in which the lesions are not symmetrical and in which the paroxysmal character of the attacks is not well marked often present great difficulty. Slight cases of frostbite or of 'dead fingers' differ only in degree from true cases of local syncope. Local cyanosis may be simulated by the cyanosis of *morbus ceruleus*, but here the blueness is seen in the lips and other parts, the nails are blue, the finger-ends are clubbed and painless, and there are the usual auscultatory evidences on examination of the heart. In erythromelalgia the altered colour of the part is induced by the dependent position; the temperature of the part is raised, the affection is usually unilateral and is more common in men than in women. Symmetrical gangrene may be mistaken for gangrene depending on arteritis, cardiac weakness, diabetes or embolism; but in all these cases the lesions are rarely symmetrical, and if so are accompanied by gross changes in the heart or arteries, or occur at a period of life in which Raynaud's disease is rare, or there is evidence in the urine of the presence of sugar. Ergotism may simulate Raynaud's disease, but may be excluded by the investigation of the food and by the epidemic nature of the outbreaks of ergotism. In all doubtful cases the paroxysmal nature of the attacks, the symmetry of the affected parts, the age of the patient, and the absence of evidences of other

vascular disease will enable us to recognise cases of Raynaud's disease. The existence of evidence of loss of substance of the ears, fingers, or toes may render us valuable assistance in satisfying ourselves as to the nature of an attack of local syncope, cyanosis, or gangrene.

PROGNOSIS.—The disease is rarely fatal. Many cases recover entirely; others remain liable to recurrences for years. Death, if it occurs, is usually the result of some complication, such as Bright's disease, pulmonary tuberculosis, carcinoma, exhaustion, diarrhoea, and occasionally of scleroderma or of the extension of the gangrenous process.

It must be remembered that Raynaud's disease, though it may not shorten life, may render the unfortunate sufferer incapable of performing the ordinary duties of life for a considerable period, and may make residence in cold climates during the winter most undesirable.

TREATMENT.—This may be considered under two heads: the treatment during the attacks, and the treatment during the intervals between them.

During an attack treatment by electricity has proved successful. Barlow advises that the part should be immersed in a basin containing warm salt-solution, and that the negative pole of a galvanic circuit should be placed in the basin, while the positive pole is placed on a healthy part of the patient, such as the nape of the neck, or on the limb above the affected part. The current should be as strong as can be comfortably borne, and should cause some contraction of the muscles of the limb. It should be frequently interrupted and reversed, and the patient encouraged to move the affected parts. The galvanisation should be continued till the part is red, and then the part should be gently rubbed and dried. Barlow recommends this treatment both during the attacks and in the intervals between them. Faradism has also proved useful, as has galvanisation of the sympathetic in the neck. Friction and massage of the affected parts, if it can be borne, may cut short an attack, and render fresh attacks less likely to occur. Warmth during an attack often increases the pain. These cases may not infrequently be relieved by cold applications. Laudanum or chloroform sprinkled on moist compresses, or glycerine of belladonna painted on the part, and even oxygen-baths, have all given relief in some cases, but nothing has been so successful as the electrical treatment. Hypodermic injections of morphine, with or without atropine, into a healthy part have been useful in relieving pain. The part must be protected from cold and injury. In slight or early attacks brisk exercise may ward off an attack. Vasodilators, such as amyl nitrite, nitroglycerine and the other nitrites, have proved of little use during the attacks.

In the intervals between the attacks patients should be careful to protect the hands from cold by means of loose woollen gloves and mittens, and the feet by warm socks. Patients should avoid exposure to cold, and should use warm water for washing. Exercise, a generous diet and a moderate use of alcohol are all advisable. In malarious districts quinine in doses of 10–20 grains (in solution) has been successfully employed, as has opium administered regularly in small doses. In cases where syphilis is suspected of being the determining factor, mercury and iodide of potassium have been of use, though in the experience of the writer neither drug

has had any beneficial effect on the paroxysmal hæmoglobinuria or the Raynaud's phenomena. In those who suffer in the cold weather residence during winter months in warm climates may be necessary to prevent recurrences. When gangrene occurs the parts should be simply protected by some aseptic dry material, and any irritant dressing should be carefully avoided. Amputation—rarely necessary—should be performed only when the part is actually dead and the surrounding parts are healthy.

ARTHUR FRANCIS VOELCKER.

RECEPTACULUM CHYLI, Diseases of.—

The only morbid conditions which need be specially noticed in connection with the receptaculum chyli are *dilatation* and *rupture*. It has been found in rare instances enormously dilated, and its walls thickened (*see* FILARIASIS). It has also been known to burst as a result of this dilatation, with the escape of its contents into the peritoneal cavity, fatal peritonitis being thus set up.

FREDERICK T. ROBERTS.

RECEPTION ORDER for Lunatics.—*See* LUNACY, Law of.

RECKLINGHAUSEN'S DISEASE.—A name occasionally employed to denote multiple neurofibromata of the skin.

RECOARO, in the Province of Vicenza, in Italy.—Chalybeate waters. *See* MINERAL WATERS.

CRUDESCENCE (*re-*, again; and *crudescere*, I become fresh).—The increase or exacerbation of a disease or morbid process, after a temporary diminution; for example, of fever or inflammation.

RECTUM, Diseases of. — **SYNON.**: *Fr. Maladies du Rectum*; *Ger. Krankheiten des Mastdarms*.

The diseases of the rectum may be conveniently discussed in the following order: (1) Congenital Imperfections; (2) Fistula in Ano; (3) Cancer; (4) Polypus; (5) Prolapse; (6) Non-Malignant Stricture; and (7) Ulceration. Other diseases connected with the rectum will be found discussed under special headings. *See* ANUS, Diseases of; DEFÆCATION, Disorders of; HÆMORRHOIDS; and STOOLS, Characters of.

1. **Congenital Imperfections.**—Malformations of the rectum may be classed as follows: (1) Imperforate anus, without deficiency of the rectum. (2) Imperforate anus, the rectum being partially or wholly deficient. (3) Anus opening into a *cul-de-sac*, the rectum being partially or wholly deficient. (4) Imperforate anus in the male, the rectum being partially or wholly deficient, the bowel communicating with the urethra or neck of the bladder. (5) Imperforate anus in the female, the rectum being partially deficient, and communicating with the vagina. (6) Imperforate anus, the rectum being partially deficient, and opening externally in an abnormal situation by a narrow outlet. (7) Narrowing of the anus. These imperfections can be remedied either partially or completely by surgical operations.

2. **Fistula in Ano.** — **DESCRIPTION.** — The loose areolar tissue around the lower part of the rectum is occasionally the seat of abscess, which bursts externally near the anus (*see* PERIPROCTITIS),

But instead of the part healing afterwards, like abscesses in other situations, the walls contract and become fistulous, and the patient is annoyed by a discharge from the opening. On introducing a probe it may pass through a small opening in the coats of the rectum into the bowel. The case is then called a *complete fistula*. When there is only one aperture, either mucous or cutaneous, the term *incomplete fistula* is used. The external orifice is usually near the anus, the internal between the two sphincters. The abscess before bursting may have urrowed to some distance, and the external orifice may be situated in the direction of the buttock or perinæum. Fistula in ano arises in several ways. It commonly originates in an abscess in the ischio-rectal fossa, the anatomical condition of the parts not favouring closure after the pus has escaped. An ulcer just within the external sphincter sometimes perforates the bowel, allowing the escape of feculent matter into the areolar tissue, and thus leads to abscess. Ulceration induced by a pointed foreign body, as a fish-bone, may also induce a rectal abscess. Fistula is common in the late stages of rectal cancer. Fistula occurs also in phthisical subjects, owing to tubercular mischief in or around the rectum. This tuberculosis may be primary or secondary, and in the discharge from such fistulæ the *Bacillus tuberculosis* has been found. The inner opening is sometimes found higher up the bowel, and there may be more than one, the sinuses being complicated.

An anal fistula is an annoying complaint. The patient is troubled with a discharge which stains the linen, and with the escape of flatus. Attacks of inflammation and suppuration are common, and the trouble produces often great mental depression, and much constitutional disturbance. Fistula is a disease of middle life, more common in men than in women.

TREATMENT.—The cure of fistula in ano is by a surgical operation.

3. Cancer.—Cancer of the rectum is common; appears with about equal frequency in males and females; and is an affection of middle life or old age. The form of cancer is that known as cylindrical epithelioma or adeno-carcinoma; and the most conspicuous feature is the infiltration of the sub-mucous and muscular coats. The growth may appear as a nodular mass springing from one side of the rectum, and more or less occupying its lumen; or it may assume the aspect of a laminar deposit in the rectal walls; or may take the form of an annular growth. The deposit tends to narrow the bowel, and is disposed to early ulceration. The growth may invade and open the vagina, urethra, or bladder, and is in time attended by glandular enlargements. Malignant disease may attack any part of the bowel, but generally appears in the lower part, within three inches of the anus. It is liable also to affect, though less frequently, the point where the sigmoid flexure terminates.

SYMPTOMS.—The disease generally commences insidiously. Its early symptoms are often similar to those of simple stricture, and the real disease is usually not detected until a considerable change has taken place in the condition of the bowel. The patient is troubled with flatulency; has difficulty in passing his motions; and as the disease progresses, experiences pains about the sacrum, which gradually increase in severity, and dart down the limbs. The stools become relaxed and frequent; contain blood;

and in passing cause a scalding pain. Often also there is a thin offensive serous or sanious discharge. The first symptom complained of may be an obstinate diarrhoea. Loss of retentive power may ensue, from destruction of the sphincter, or of the nerve supplying the muscle. As the disease advances the patient loses flesh, and exhibits the blanched, sallow look, anxious countenance, and emaciated appearance commonly observed in persons suffering from malignant disease. In consequence of communications established with the neighbouring passages, liquid feces may escape from the urethra in the male and vagina in the female; and at length the patient becomes exhausted by this painful and distressing malady. Complete obstruction may occur, and accelerate the fatal termination. There is great variety in the degree of suffering, and of constitutional derangement. The pains are in some instances excruciating, in others very slight. If the growth can be reached by the finger, it will be found to present a hard, nodular, uneven, and ulcerated surface, and to become soon fixed.

TREATMENT.—Little can be effected by remedies in this terrible disease, beyond palliation of the symptoms, and ease from pain. The general health must be supported. The motions must be kept soft by medicines or by injections, and pain must be alleviated by narcotics, such as morphine given in suppositories or by subcutaneous injection. Local applications of cocaine answer well in some cases. The diet must be carefully regulated so that as little *débris* as possible is left in the intestine, and the bowel should be frequently irrigated with some antiseptic injection. In cases of obstruction, as well as in cases of severe suffering, life may be greatly prolonged by inguinal colotomy. Excision of the diseased bowel has also been resorted to, but not with much success.

4. Polypus.—Non-malignant tumours of the rectum are apt to assume a polypoid form and are generally classed under the heading 'polypus.' Polypus of the rectum may be conveniently considered under three headings: (1) *The soft polyp or adenoma*. (2) *The firm polyp or fibroma*. (3) *The villous polyp or papilloma*. They are all innocent growths.

DESCRIPTION.—(1) *The soft polypus* is a true adenoma, with a network of small vessels ramifying in it, and a pedicle which varies in length. The polypus is usually single, but several may exist. In children it usually makes its appearance at the anus after a stool, resembling a small strawberry, being soft in texture, granular on the surface, and of a red colour. It has a narrow pedicle, about the size of a crowquill, attached to the wall of the rectum, as a rule about two inches from the anus. It produces no suffering, but causes a slight bloody discharge, some tenesmus, and a sense of a foreign body in the bowel. It is the commonest form of polyp.

(2) *The hard or fibrous polypus* occurs in adults, is pear-shaped, and has a pedicle more or less long and thick. It seldom bleeds, but occasions a slight mucous discharge, and when the pedicle is long, the growth protrudes at the anus after stool. It is uncommon; and is due to a fibrous growth in the submucous tissue.

(3) *The villous polyp* is a pure papilloma developed from the mucous membrane of the rectum. It is soft in structure, presents the usual appearance

of a papilloma, and may have a pedicle, but is usually sessile. It is rare, is met with in adults, and is innocent. It gives rise to considerable bleeding, and usually to a mucous discharge, and the symptoms of a foreign body in the bowel. There is no doubt but that it may in time become the seat of malignant changes.

Myoma, myxoma, lipoma, cystoma, and nævus are also met with in the rectum.

TREATMENT.—The treatment involves an operation of small magnitude, as in the case of polyp in other situations.

5. Prolapse.—In relaxed states of the sphincter muscle and coats of the bowel, loose folds of mucous membrane are liable to protrude, and require replacement. This protrusion and exposure of thickened mucous membrane, with or without internal hæmorrhoids, has been described as partial prolapse of the rectum. In the true or complete prolapse there is much more than an eversion of the lining membrane of the bowel. The gut is inverted; there is a 'falling-down' and protrusion of the whole of the coats—a change analogous to intus-susception, but differing from it in the circumstance that the involved intestine, instead of being sheathed or invaginated, is uncovered and projects externally. In the majority of instances the prolapse, even when extensive, concerns the mucous membrane only.

ÆTIOLOGY.—Prolapse is observed generally between the ages of two and four, but may occur later in life. In infancy it may be produced by protracted diarrhoea or by worms. The straining efforts to pass water in stone in the bladder also give rise to this affection in young subjects. In adults the descent results chiefly from a weakened condition of the sphincter and levator ani muscles. It is more common in women than in men, arising in the former from the parts being weakened in child-bearing. It may follow also upon dysentery, upon conditions producing straining, and upon rectal polyp. Young subjects generally outgrow this complaint by the period of puberty; and common as is prolapse in early life, it is rare in young adults.

DESCRIPTION.—The length of bowel protruded varies from an inch to six inches or even more. When not of any great length, the protrusion forms a rounded swelling which overlaps the anus, at which part it is contracted into a neck. In its centre there is a circular opening communicating with the intestinal canal. An inversion of greater length forms an elongated pyriform tumour, the free extremity of which is tilted forwards or to one side. The protrusion may present the usual florid appearance of the mucous membrane; or a violet livid colour from congestion, consequent upon contraction of the sphincter. The mucous surface is often thickened and granular, and sometimes ulcerated from friction against the thighs and clothes. Thickening of the coats of the bowel accounts for the difficulty in reducing the parts, and in keeping them reduced afterwards, a trouble so often experienced in the treatment of these cases in children, the bowel being too large to be conveniently lodged in its natural position, and, like a foreign body, exciting the action of expulsion. An atonic or relaxed state of the sphincter muscle is shown by the facility with which one or two fingers can be passed through the anus even in young children.

TREATMENT.—In children irritability of the bowels and diarrhoea must be checked, and disordered secretions corrected by suitable remedies. In slight cases it will be sufficient to direct the nurse by steady compression to press the protrusion back within the sphincter. The relaxed state of the membrane may be treated with astringent injections of alum, or with a solution of tannic acid in glycerine, or with hamamelis. If the bowels slip down when the child moves about, rest must be insisted on. When the exposed surface is ulcerated, it may be painted with a solution of nitrate of silver, 20 grains to the ounce. The patient should be made to relieve the bowels in the recumbent posture. In adults, if no relief follows the removal of the apparent cause, the regulation of the bowels, rest, and the use of astringent applications, the complaint may be remedied by operation.

6. Non-Malignant Stricture.—Non-malignant stricture of the rectum is usually due to the development of cicatricial tissue, and has followed injuries, suppuration, dysentery, syphilis, and tubercular mischief. Cripps has shown that long-continued muscular spasm may play an essential part in the production of stricture.

Simple stricture is met with in adult life, is more common in women than in men, and is usually situated within three inches of the anus. The stricture may be *annular* or ring-like; or the obstruction may assume a *valvular* form; or a large part of the length of the bowel may be involved, producing a *tubular* stricture. The mucous coat above the stricture may be ulcerated. Often ulcerated apertures lead to fistulous passages, extending some distance, and opening externally near the anus or in the buttock, and, in women, in the vagina.

SYMPTOMS.—The earliest symptom is habitual constipation, with difficult defæcation when the motions are solid. As the contraction increases, the constipation becomes more obstinate, and the stools are diminished in calibre, and are often voided in lumps. A brown slimy fluid escapes with the motions, and there is a burning sensation after stool, and flatulent distension of the colon. As the disease makes progress and ulceration ensues, the discharges become purulent and bloody, and the sufferings are much increased. There is sometimes so copious a discharge as to mislead the practitioner, the stricture being overlooked, and the case treated as one of protracted diarrhoea. The appetite may remain good, and the general health may be but little impaired; but in the course of time the derangement of the digestive functions, the irritation kept up by the disease, and the exhausting discharges, bring on symptoms akin to hectic. The appetite fails, the body emaciates, the abdomen becomes more distended, and the stricture directly or indirectly proves the cause of death. This is sometimes hastened by a lodgment of hardened feces or some foreign body just above the stricture, so as to block up the passage, and occasion all the symptoms of intestinal obstruction. In patients with stricture small flattened excrescences are often observed at the margin of the anus. These cutaneous growths resemble collapsed external piles, except that they are redder in colour, and are kept moist by the escape of an irritating discharge from the bowel. Compared with cancer, the progress of the disease is very chronic, the edge of the stricture is hard and ridge-like, ulceration is absent or at least

is not marked, induration is slight, there is less bleeding, and less fixity of the part.

A stricture in the lower part of the rectum can be easily detected by the finger. It must be borne in mind that the bowel is liable to be obstructed by disease of the neighbouring viscera—an enlarged or displaced uterus, fibrous tumours of this organ, an ovarian growth, pelvic hæmatocele, excessively hypertrophied prostate, or hydatid tumour between the bladder and rectum.

TREATMENT.—The main object in treatment is to dilate the contracted parts sufficiently for the free passage of the motions; and this is to be effected by mechanical means—by the frequent passage of bougies, or the occasional use of special dilating instruments. Means must also be adopted to relieve the irritability of the part, and to ensure the regular passage of soft evacuations. Cocaine, belladonna, or morphine suppositories at bedtime, properly selected aperients, careful dieting, and the daily washing out of the bowel, are the remedies required. In cases which resist such measures as are indicated operation may give relief. In old inveterate strictures, wearing out the patient's strength, colotomy may be recommended.

7. Ulceration.—The chronic ulcers met with in the rectum are the following: The *tubercular*, the *syphilitic*, the *dysenteric*, those due to *injury*, *suppuration*, or *fecal impaction*, the *hemorrhoidal*, which has the same pathological basis as the varicose ulcer of the leg, and ulcers associated with chronic diarrhœa, stricture and inflammatory troubles in adjacent parts.

These ulcers have the physical characters of like ulcers met with elsewhere. The tubercular ulcer is very apt to perforate. The chief symptoms are a purulent discharge from the anus; motions loose and mixed, or coated with a slimy fluid and streaked with blood; soreness in defæcation; and occasionally tenesmus. Morning diarrhœa is often one of the earliest symptoms. A burning pain in the rectum is complained of, and often radiating pains about the hips. The characters, position, and extent of the ulceration can be ascertained by examination with the finger and with the speculum. The examination, to be satisfactory, must be conducted when the patient is anæsthetised.

All forms of non-malignant ulceration are more common in women than in men.

TREATMENT.—The treatment depends on the nature and extent of the disease, and upon the constitutional condition of the patient. In severe cases the patient should be kept in the recumbent position, and the diet should be regulated. An exclusively fluid diet may be desirable in some cases. The bowels must be attended to. The local treatment consists of antiseptic or astringent injections or ointments. Weak solutions of nitrate of silver are of value, as are also injections of bismuth mixed with starch. Iodoform or other ointment may be applied by means of an ointment-introducer. Obstinate forms of ulcer may be treated by free scraping or by even more extended operation.

FREDERICK TREVES.

RECURRENT LARYNGEAL NERVE, Diseases of.—See PNEUMOGASTRIC NERVE, Diseases of.

RED GUM.—See STROPHULUS.

REDUPLICATION.—A doubling. A term generally used in reference to the sounds of the heart. See PHYSICAL EXAMINATION.

REDUX (Lat., returned).—A term signifying the return of certain physical signs, after their temporary disappearance in the course of a disease; usually associated with crepitation in pneumonia, and with friction in pleurisy and pericarditis. Redux signs are, as a rule, significant of a favourable tendency in a disease. See PHYSICAL EXAMINATION.

REFLEXES.—See NERVOUS SYSTEM, Clinical Examination of; and SPINAL CORD, Diseases of.

REFRACTION, Disorders of.—See VISION, Disorders of.

REFRIGERANTS (*refrigero*, I cool).—DEFINITION.—Remedial agents which lower the body-heat, either in health or in disease; or which allay thirst, and impart a feeling of coolness.

ENUMERATION.—The chief refrigerants are: The whole class of Febrifuges; Water; Ice; Effervescent drinks; Acidulated drinks; and the juices of Fruits.

ACTION.—As the name implies, anything may be ranked as a refrigerant which lowers the body-temperature, and we may here consider in how far the drugs described under FEBRIFUGES have the property of cooling down the healthy organism. Quinine and alcohol have but a slight and transient lowering effect, and salicylic acid has none at all; and this is readily explained, if we believe that their antipyretic properties in fever depend on their destructive influence over the protoplasm or products of septic ferments.

Refrigerants, however, are popularly held to be those drugs which relieve the thirst of the fever-stricken patient, by moistening his dry lips and cooling his parched tongue. Ice or iced-drinks manifestly fulfil these indications; and acids well diluted, which are often the most grateful of all, act very efficiently by directly stimulating the salivary secretion.

R. FARQUHARSON.

REGIMEN (*rego*, I govern).—This word is not uncommonly used as synonymous with hygienic management. In a more restricted sense it is applied to the regulation of diet, both in health and disease. See DIET; and PERSONAL HEALTH.

REGURGITATION (*re-*, back again; and *gurgilo*, I flood).—This word is technically applied to the reversal of the natural direction in which the current or contents flow through a tube or cavity of the body. Thus the food may regurgitate from the stomach into the œsophagus and mouth; the bile from the duodenum into the stomach; and blood from the aorta or pulmonary artery into the ventricles, from the ventricles into the auricles, or from the heart into the veins, when the respective valves are incompetent. See HEART, VALVES AND ORIFICES OF, Diseases of; and RUMINATION.

REHME (Oeynhausens), in Germany.—Gaseous thermal salt waters. See MINERAL WATERS.

REICHENHALL, in the Bavarian Alps.—Common salt waters. See MINERAL WATERS.

REINERZ, in German Silesia.—Chalybeate waters. See MINERAL WATERS.

RELAPSE (*re-*, back; and *lapsus*, slipping).—The return of a disease, which has apparently ceased, during or immediately after convalescence; or of a particular symptom in the course of a disease. Relapses are well exemplified in typhoid fever and acute rheumatism.

RELAPSING FEVER.—**SYNON.**: Famine-Fever; Fr. *Fièvre à Rechute*; Ger. *Hungerpest*.

DEFINITION.—An acute infectious disease, due to the presence of a minute parasite, the *Spirillum Obermeieri*.

GEOGRAPHICAL DISTRIBUTION.—Northern Europe was the favourite habitat of relapsing fever. It has been met with in America, but not as an epidemic, having been imported from Europe, and not showing a tendency to spread. Epidemics have occurred in India and in Egypt, and were once common in the British Isles. The most extensive epidemics have arisen in Ireland in times of famine, and extended thence to England and Scotland. An epidemic was confined to Scotland in 1843, and another to London in 1868.

ETIOLOGY.—*Predisposing Causes.*—Males suffer more from relapsing fever than females, in the proportion of about 1·5 to 1. The disease is most common between the ages of fifteen and twenty-five. Season seems to have little effect, but it appears to be more prevalent in winter than at other seasons, because the other predisposing causes are more intense at that time of the year. All the causes which predispose to contagious zymotics favour more or less the prevalence of relapsing fever. The most powerful, however, are scarcity of food, overcrowding, and want of cleanliness.

Relapsing fever is contagious, and has always been found to spread in proportion to the facilities for communication. It has been transported from long distances by affected persons; it attacks attendants on the sick, and any persons exposed to its contagion; and it may be communicated by fomites. It seems to act through but a short distance.

A spirillum—*Spirillum* or *Spirochæte Obermeieri*—is found in the blood of patients suffering from relapsing fever. This micro-organism decreases in number as the paroxysms subside, and is absent from the blood during the intermissions. The spirillum was discovered by Obermeier of Berlin in 1872.

Description of the organism.—The spirillum is of considerable length, measuring '1½ to 6 times the diameter of a red blood-corpuscle,' but is exceedingly thin. It shows several regular somewhat abrupt curves, and is of uniform thickness, except at the extremities, where it is pointed. It is possessed of very active motility, having both a wavy and spiral motion, and being also capable of rapid locomotion. At the onset of and during the fever the spirilla may be present in the blood in enormous numbers. The organisms always occur free, being never found within either the red corpuscles or the leucocytes. In dried films of blood they can be stained by any of the simple stains, though they do not take the colour very deeply; but in sections of the tissues their demonstration is a matter of considerable difficulty, and one of the methods for avoiding decolourisation requires to be used, methylene blue being a suitable

dye. They are decolourised by Gram's method. Koch succeeded in staining them in the tissues with Bismarck brown.

In blood outside the body the spirillum has considerable vitality, sometimes showing active movements after several days. It is killed by a temperature of 60° C., but it can be exposed to 0° C. without being killed.

Relations to the disease.—All attempts to cultivate the organism outside the body have hitherto failed. Koch observed that in certain conditions a growth of the organism in length took place, but no actual multiplication. Soon after its discovery, however, Münch, by injecting blood containing the organism, produced the disease in the human subject; and a little later Vandyke Carter and Koch produced the disease in apes by a similar procedure. In such cases there is an incubation-period usually of three to six days before symptoms appear. In all cases, along with the onset of the fever, the spirilla appear in the blood in enormous numbers. As a result of these observations and experiments it may be considered as practically proved, even in the absence of pure cultivations outside the body, that this organism is the cause of the disease.

As already mentioned, the organisms disappear from the blood about the time of the crisis, and are absent during the 'interval.' Metchnikoff, by producing the disease in apes and killing them at various stages of the fever, found that during the period of defervescence the spirilla on disappearing from the blood accumulated in the spleen, and he alleged that they were incorporated within leucocytes in that organ. Within these cells he observed spirilla in various stages of disintegration. This process of 'phagocytosis' never occurs, according to him, in the blood, and after the spirilla have disappeared from the blood they are not present in any other organ than the spleen. Soudakewitch has performed similar experiments, and obtained practically the same results. It is, however, still unexplained why the disappearance of the organisms from the blood should start at a particular time, and should then take place so rapidly. This and other peculiarities suggest a comparison between this disease and malaria, and it has even been supposed that the parasite is a protozoon and is conveyed through the agency of insects.

ANATOMICAL CHARACTERS.—These are not marked, except where complications have caused death. The liver and spleen are both found enlarged in all cases, especially the latter organ. The digestive organs exhibit nothing particular, except in those cases where there has been long deprivation of food, or where dysentery or diarrhoea has accompanied or preceded the disease.

SYMPTOMS.—The period of incubation is uncertain, varying between one and twenty-one days. The invasion of the disease is usually marked by rigors, frequently of a trivial character, amounting only to slight chilliness. This is followed by debility and giddiness; extreme weakness is not so marked as in the early stages of other forms of continued fever. There is headache, followed after a few hours by hot skin; the temperature rises to about 105° F., or sometimes, it is stated, as high as 108°; the pulse rises to from 110 to 130, occasionally even to 140 at an early stage of the disease. The tongue is covered with a moist creamy fur, which in severe cases becomes brown

and dry in the centre, and in the worst forms becomes black all over. There is great thirst, as in all febrile diseases; loss of appetite; some abdominal tenderness, especially in the epigastric region; occasionally nausea, and more rarely vomiting; the bowels are usually confined, but in some cases diarrhoea prevails. In such cases the diarrhoea is of a dysenteric character, and is probably due to the dysenteric tendency which usually prevails in time of famine, when relapsing fever is prevalent. The skin generally presents a jaundiced hue; and careful examination will detect more or less enlargement of the liver and spleen. There is great muscular and articular pain. The pain in the back is frequently of the most intense character. Headache is more complained of than in the other forms of fever. There is sometimes, but not as a rule, delirium towards the end of the first week.

In from five to seven days from the invasion of the disease the symptoms suddenly subside, and the patient quickly becomes convalescent, being for the time apparently well. This convalescence is frequently accompanied or preceded by a critical evacuation from the bowels, kidneys, or uterus, or by profuse diaphoresis. It may be permanent, but more commonly the patient remains well for a few days or a week, and then suddenly relapses, and passes through all the symptoms previously detailed. There may be a second or a third relapse, and even a fourth has been recorded. At no time during the progress of the disease is any specific eruption developed, although on the second or third day a reddish mottled rash has been met with, which, however, is irregular in its appearance, development, and duration, and usually terminates in desquamation. Purpuric spots have been sometimes, and sudamina very frequently, met with.

COMPLICATIONS.—Pulmonary complications are not so common in relapsing fever as in typhus or enteric fever. Bronchitis, pneumonia, and laryngitis may occur, especially bronchitis, but these complications are not severe. Cardiac, arterial, or venous affections are rare, with the exception of hæmorrhages, which must be considered as being connected with the purpuric tendency which usually prevails in times of scarcity. Nervous complications are more rare than in any other form of adynamic fever. Dysentery and diarrhoea in some epidemics have proved to be most serious complications, and are of frequent occurrence whenever relapsing fever prevails. Abscess and other suppurative forms of inflammation are not common. In pregnant females attacked by this fever abortion usually occurs at an early stage of pregnancy; and premature labour, with death of the fœtus, and considerable danger to the mother, in the later stages of pregnancy. Death of the mother has sometimes happened from *post-partum* hæmorrhage.

DIAGNOSIS.—Relapsing fever is most likely to be mistaken for other forms of continued fever, and may be confounded with the eruptive fevers in their earlier stages, especially small-pox. It differs from typhus in having a higher temperature and quicker pulse at the outset; in the absence of the specific eruption, of the extremely heavy aspect of the patient, and of the delirium of typhus; in the presence of extreme pains in the back, vomiting, and jaundiced tinge of the skin; and finally in the sudden cessation of symptoms, and the tendency to relapse.

Relapsing fever differs from enteric fever in the suddenness of its onset, enteric fever having a slow invasion; the want of the marked and extensive daily variations in temperature; the absence of the characteristic abdominal symptoms and eruption; and the absence of the localised iliac tenderness and the peculiar diarrhoea of enteric fever. The tongue also serves to distinguish relapsing from enteric fever; in the latter having a well-marked red tip and edges, in the former a light covering fur. Relapsing fever at its commencement has been confounded with small-pox, on account of the extreme pain in the back and marked vomiting which accompany both these diseases, but the appearance of the specific eruption will soon decide the question.

PROGNOSIS, DURATION, TERMINATIONS, AND MORTALITY.—The prognosis of relapsing fever is usually favourable, the mortality being low, from 1·2 to 2 per cent. in London, up to 4 and 4·5 per cent. in other places; the average rate being about 4 per cent. The chief causes influencing the rate of mortality seem to be the prior state of the patient, and the duration of the disease before medical relief is applied for. Purpuric symptoms, severe dysentery or diarrhoea, serious hæmorrhages, or extensive chest-complications, always indicate a grave prognosis. One attack confers no immunity.

TREATMENT.—The treatment of the disease must be preventive and curative. The chief promoting causes of the disease being famine and contagion, the means for prophylaxis are obvious. The active treatment must chiefly be directed towards the relief of symptoms, and sustaining the strength of the patient. The use of quinine and mineral acids in the earlier stages, and a plentiful supply of light and nourishing food in the later, will be found sufficient. A considerable amount of the success of treatment will depend upon the dieting of the patient. It must be kept in mind that most of these patients have been in a state of starvation. It will be necessary, therefore, to increase the supply of food carefully and gradually. The food at first must be of a most digestible and fluid kind, which may gradually be altered to a diet of a more solid and general character. Milk, light starchy puddings made with milk, thin custards, and finally chicken, chops, and general diet will be found the best course in this disease. Stimulants may be occasionally requisite, but are seldom necessary in any quantity or for a length of time.

T. W. GRIMSHAW.

REMITTENT (*re*-, again; and *mitto*, I send).—A disease is said to be remittent when it is characterised by periodical diminutions of symptoms, followed by exacerbations, as in malarial fever and neuralgia. The period during which the symptoms are in abeyance is called a *remission*. See **MALARIAL DISEASE**.

REMITTENT FEVER.—See **MALARIAL DISEASE**.

RENAL CALCULUS.—**SYNON.**: Nephrolithiasis; Fr. *Calcul Rénal*; Ger. *Nierenstein*.

DEFINITION.—A concretion found in the substance, in one of the calyces, or in the pelvis of the kidney. This concretion is due to the deposition of one or more of the crystalloid substances from the urine.

The size depends upon its position, the shape upon its position and composition. Calculi may be present in one or both kidneys. They may occur at all ages, and are rather more common in the male sex.

ÆTIOLOGY.—In some instances the nucleus of the calculus consists of a blood-clot, of epithelial cells, or of mucus, upon which the crystalline constituents of the urine are deposited. The separation of the solid constituents is favoured by sedentary habits, by gout, and by other conditions which produce either a change in the reaction of the urine or an excess of uric acid, calcium oxalate, or other constituent of calculi. An excess of nitrogenous or saccharine food, or of salts of lime, or an insufficient supply of liquid, will also increase the tendency to deposition. Irritation of the kidney or renal pelvis by inflammation or injury, by affording a nucleus, aggravates any hereditary tendency to the formation of renal calculi. Dietetic errors and metabolic disturbances are regarded as predisposing causes, while pyelitis or other local change is considered the immediate determining cause.

VARIETIES.—Renal calculi present great variations in composition, in number, in size, and in appearance; and these variations to some extent are dependent upon the age at which they become manifest, and upon the duration of their retention at the original site of their formation. They are most frequently found to consist of uric acid, especially when formed during adolescence. In childhood, however, the nucleus commonly consists of ammonium or sodium urate. Calculi composed of calcium oxalate are more common after middle age, and this substance is often regarded as the nucleus, even of uric acid calculi; it is probable, however, that the nucleus is generally some result of local inflammation or irritation. Other lime-salts, as the carbonate, the basic phosphate, and the triple phosphate, are occasionally met with, but they are generally secondary deposits upon nuclei of uric acid or calcium oxalate; they occur when the urine has become alkaline. When the alkalinity is fixed the carbonate and basic phosphate will probably be deposited, while triple phosphate is more frequent when the alkalinity is due to the development of volatile ammonium-compounds. Very rarely calculi may consist of cystin, xanthin, or indigo (p. 333).

When a single renal calculus is found it may be rounded, oval, or slightly nodular if composed of uric acid; if consisting of calcium oxalate the surface is generally more irregular, constituting the 'mulberry' calculus. When several calculi are present, they may have distinct facets, or if small and numerous, they may form irregular granular masses, or they may even be so small as to be designated 'sand.' When long retained in the pelvis of the kidney, the shape may become extremely irregular, processes forming between the pyramids, or projecting towards the ureter. Calculi with secondary deposits may attain great size, and may present alternating strata, phosphates generally constituting the external part. The formation of secondary deposits tends to obscure primary irregularities, and to render the calculus more smooth and round or oval.

PATHOLOGICAL EFFECTS.—The consecutive renal changes depend upon the composition and mobility of the calculus. When small it may become embedded or buried in the renal tissue, and for a length of time may cause no material change be-

yond some local thickening due to chronic interstitial nephritis. Ordinarily, however, it causes some degree of obstruction, which is followed by dilatation of the renal pelvis (hydronephrosis). In either case more active inflammation may be excited, and pyelitis, pyelonephritis, or perinephritis may result, with consecutive atrophic changes. Under these conditions there may be considerable destruction of renal tissue, especially when suppuration is pronounced. Although these changes are primarily limited to one side, the opposite kidney frequently becomes similarly involved, especially when the original calculus is composed of uric acid or urates.

SYMPTOMS.—When the calculi are small they may occasionally be passed without causing any symptoms. Larger concretions, embedded between the pyramids, may also cause no symptoms, but usually there is complaint of unilateral pain referred to the region of the kidney, and subject to exacerbations with moderate movements or with unsuitable diet. The lumbar pain, which is so often met with in gouty patients, is probably due to the presence of renal calculi. These attacks of renal pain are sometimes very acute, and during the attack the pain may radiate along the ureter to the groin and testicle, or it may be referred to the thigh, the calf, or the foot. When, however, there is definite obstruction in the ureter, the result of the passage of a calculus or of a plug of mucus, renal colic is excited, in which the pain is of an agonising character, and frequently accompanied by nausea, vomiting, and hæmaturia. Renal colic is due to the spasmodic contractions of the ureter, and, although it results ordinarily from the displacement of a calculus, it does not invariably indicate that the calculus has actually passed from the pelvis to the ureter; severe spasm may be excited so suddenly that the onward progress of the calculus may be thereby obstructed. The pain is primarily referred to the region of the kidney and the ureter on the affected side, and may cause retraction and tenderness of the testicle. Occasionally it can scarcely be localised; it appears to radiate through the abdominal cavity, and may even be referred to the umbilicus. The duration of renal colic is extremely variable. It may last only for a few hours, being followed by aching or soreness in the course of the ureter, or it may continue, with periods of partial relief and with exacerbations, for several days. There may be sudden relief, especially after a fit of vomiting, when the stone has passed into the bladder, but even this is ordinarily followed by discomfort along the ureter. With the onset of renal colic there is frequent desire to micturate, and there may be tenesmus; the urine is passed in small quantity, and is commonly intimately mixed with blood. Occasionally, however, when there is complete obstruction of one ureter, the urine may remain clear. Cases of suppression of urine are by no means uncommon after repeated attacks of renal colic upon both sides of the body. In these, for five or six days, there may be no symptoms beyond the partial or complete arrest of excretion, and then uræmic symptoms develop, such as hiccough, vomiting, and muscular spasms. The temperature falls, and death may occur between the ninth and twelfth days from failure of respiration and circulation. Convulsions are uncommon with calculous anuria. With repeated attacks of renal colic the urine frequently becomes turbid with pus owing to pyelitis.

DIAGNOSIS.—Renal calculus may be mistaken for recurrent attacks of intestinal colic, for biliary colic, for appendicitis, for lumbago, for tubercular or malignant growth of the kidney, or for hydronephrosis due to some abnormality in the position or length of the ureter. The indications upon which greatest reliance can be placed are the nature of the colic and the frequency of hæmaturia. The association of these two symptoms may render the diagnosis easy, especially when the history shows that small calculi have been passed. The site of fixed pain, and the recurrent exacerbations with sudden jolting movements, favour the diagnosis, even in the absence of hæmaturia. Frequent deposition of oxalates or of uric acid will tend to the same view. The general health suffers very little in renal calculus, as compared with tubercular or malignant growths; when complicated with pyelitis or other suppurative change the deterioration is more marked. Recurrent hæmaturia with comparatively little lumbar pain may be mistaken for chronic nephritis, with sub-acute attacks: the diagnosis is to be based upon the absence of arterial change, of displacement of the apex-beat, and of alteration in the cardiac sounds. With movable kidney and with hydronephrosis from alterations in the ureter, the character of the pain is frequently indistinguishable from renal colic the result of calculus; often the uncertainty is so great that surgical measures are undertaken on the probability of an embedded calculus. In doubtful cases the X rays may afford assistance; but they frequently fail even when subsequent operation has proved the presence of a calculus. *See RÖNTGEN-RAYS.*

PROGNOSIS.—The prognosis is extremely uncertain. Calculi have been found after death when no symptoms have resulted from their presence. The irritation in the kidney may be so slight that, suitably treated, there is little risk. On the other hand the frequent recurrence of pain, when calculi have been passed, and the transference of pain to the opposite side render the prognosis more grave. Persistent slight albuminuria, or the development of pyelitis, will also add to the risk. When the aim has been bilateral the danger of calculus suppression must be borne in mind. The prognosis is most hopeful when, after the passage of a calculus and its removal by surgical measures, there is prolonged freedom from pain and from deposition of oxalates or oxalates.

TREATMENT.—The treatment of renal calculus may be considered under separate headings: (1) Medicinal; (2) Hygienic and dietetic; (3) Surgical. The medicinal treatment must depend upon the symptoms at the time advice is sought. Generally the first indication is the relief of a severe attack of renal colic. The pain may be controlled to some extent by the frequent subcutaneous injection of small doses of morphine. These are preferable to large single dose, which may perhaps increase the severity of vomiting. Simultaneously a hot bath could be employed, or if this is not convenient muscular relaxation may be promoted by a hot pack. To diminish the acid character of the urine, and thus to favour relaxation of spasm, copious draughts of milk, of water, or of dilute alkaline solutions are often recommended; frequently, however, reflex vomiting is so persistent that it is impossible to carry out this treatment. The pain may be so severe that relief may be sought from the administration of an anæsthetic; this rarely gives

much satisfaction although it affords temporary ease. The utmost that can be said in its favour is that it may allow time for the excretion of fluid, which, during the muscular relaxation, may favour the dislodgment of the calculus.

The medicinal treatment during the intervals between attacks of colic is similar to the treatment of gout. An alkaline course is often recommended, and to prevent fresh depositions patients often resort to foreign spas, where alkaline waters are reputed to possess solvent properties. Carlsbad, Vichy, Contrexéville, Ems, and Wildungen may reduce the frequency of attacks, and may prevent the formation of fresh calculi. It must be admitted, however, that in spite of all that has been said in their favour, or in favour of the administration of alkalis, there is no evidence that it is possible to dissolve or to reduce the size of calculi which have already been formed.

Potassium citrate has been given at night in drachm-doses, to reduce the acidity of the morning urine, and many have recommended various compounds of lithium, of potassium, and of calcium with the same object. More recently piperazine, lycetol, lysidine, chinotropine, and urotropine have been largely employed to favour diuresis and to exert solvent action on uric-acid calculi. The last named, urotropine, is frequently of service when the calculi have caused pyelitis.

Similarly hygienic and dietetic measures control the tendency to the formation, but cannot effect a cure. After recovery from an attack of renal colic active open-air exercise should be encouraged to promote metabolism, and the patient should lead a regular temperate life. When the urine is acid, meat should be taken sparingly and the daily amount of water, simple or alkaline, should be increased. Although vegetables are usually recommended, care must be taken to ascertain, if possible, the nature of the calculus which may have been passed, since if it consists of oxalates or phosphates many vegetables and fruits must be excluded from the dietary. Any tendency to obesity should be counteracted, and, partly with this object, ale and stout should not be taken. Most forms of alcohol are prejudicial to patients with renal calculus.

Surgical measures may be necessitated when frequent renal colic and hæmaturia are not followed by any evidence that the calculus has passed along the ureter, or when the renal pain is persistent and exhausting, or when sudden suppression occurs. Surgical interference may also be required when the urine assumes a purulent or a septic character. By comparatively early operation it is often possible to avert the disorganisation of the kidney which so often ensues after prolonged irritation by renal calculi. The nature of the operation must be determined after the exposure of the kidney; unless the calculi are very numerous or the disorganisation is considerable, it is generally advisable not to remove the kidney, since the opposite kidney may already have been destroyed or rendered inefficient by other calculi.

NESTOR TIRARD.

RENAL COLIC.—*SYNON.*: *Nephralgia Calculosa*; *Fr. Colique Néphrétique*; *Ger. Nierenkolik*.—The name commonly applied to the symptoms which arise when a renal calculus, blood-clot, or other substance either passes, or attempts to pass, down the ureter. *See COLIC*; and *RENAL CALCULUS*.

RENAL DISEASES.—See KIDNEYS, Diseases of.

RENNES-LES-BAINS, in France (Aude).—Muriated alkaline and earthy sulphated waters. See MINERAL WATERS.

RESISTANCE.—The sensation recognised by the fingers of the degree to which a part yields or resists when palpation or percussion is being performed. See PHYSICAL EXAMINATION.

RESOLUTION (*resolvo*, I loose).—The return of a diseased part to its natural condition; chiefly applied to the process of inflammation when it subsides without the occurrence of suppuration or other unfavourable termination. See INFLAMMATION.

RESONANCE (*resono*, I sound again, echo).—Resonance signifies the character of the sound yielded on percussion over the greater part of the chest, and, within wide limits, of the abdomen also. The degree of resonance depends principally upon the proportion of air contained in the underlying cavities or organs. *Vocal resonance* is the voice-sound transmitted through the chest to the ear of the auscultator. It is increased or diminished in accordance with the physical conditions present in the chest-cavity.

Hyper-resonance is a term used to signify undue resonance over a given part.

Deficient resonance is commonly called *dulness*. Like *hyper-resonance*, it is often used in a relative sense, in comparing the percussion-note of different parts of the chest or abdomen. See PHYSICAL EXAMINATION.

R. DOUGLAS POWELL.

RESPIRATION, Disorders of.—The numerous causes and conditions which lead to disturbances of respiration can be brought within well-defined groups, and it is desirable in the first instance to study them from such a general point of view. This, however, only gives a superficial insight into the subject, and does not indicate the kind of disorder that is produced by each cause, or how it acts, while many conditions act in more ways than one; and, still further, in any individual case there may be more than one, perhaps several causes at work, all of which ought to be recognised. These causes and conditions may be summarised in the following manner, and it will be seen that several of them act indirectly on the respiratory process:—

1. *Conditions acting directly through the nervous system.*—These include: (a) Centric lesions in connection with the brain, involving the respiratory centre, either directly or indirectly, such as injury, hæmorrhage, or a tumour. (b) Disease or injury of the upper part of the spinal cord, paralysing the nerves supplying the respiratory muscles. (c) Functional nervous disturbance, as from mere nervousness, emotion, hysteria, trance, or chorea. (d) Conditions affecting immediately the nerves concerned in respiration, either irritating or paralysing them, especially the pneumogastric, recurrent laryngeal, or phrenic nerves. These nerves may be themselves diseased, or affected by some neighbouring condition, such as a tumour. (e) Reflex causes, transmitted from the skin, as when cold water is dashed upon its surface; or from internal organs, as the

stomach, intestines, or ovaries. It is important to remember that disturbances connected with the nervous system frequently aggravate disorders of breathing originating from other causes.

2. *Abnormal conditions of the blood.*—In this group are included conditions of the blood as a whole, namely: (a) Deficient quantity of blood, especially from a sudden or rapid loss. (b) Anæmia or hydræmia. (c) Deficient aëration. (d) A poisoned, impure state of the blood associated with narcotism, the anæsthetic state, pyrexia, the typhoid condition, uræmia, pyæmia or septicæmia, diabetes mellitus, and other diseases.

3. *Functional disorders, or organic diseases connected with the heart.*—These are common sources of disturbance of breathing of various kinds, depending upon the intimate relation of the nerves and nerve-centres governing the heart and respiratory organs; upon the effects the cardiac derangements produce as regards the pulmonary and bronchial circulation; or sometimes upon the direct interference by certain affections with the movements of breathing, by exerting pressure upon the lungs, especially the left, upon the left bronchus, or upon the chest-walls, and particularly the diaphragm. This last cause is only noticed in cases of great enlargement of the heart, or of considerable pericardial effusion. The breathing, however, is frequently disturbed in connection with disorders of cardiac action; diseases of valves and orifices, especially the mitral and tricuspid; enlargements of the heart, particularly dilatation; cardiac degenerations; congenital malformations; and clotting of blood in the cavities of the heart.

4. *Abnormal conditions of the air inhaled.*—The physiological effects produced upon the respiratory act by various states of the air inspired are well known. These especially depend upon its composition; its temperature; its degree of moisture or dryness; and its condensation or degree of pressure. From a clinical point of view these effects have to be borne in mind, as they are more liable to be induced in certain diseases, and may also be made available for therapeutic purposes. The presence of certain gases in the inspired air materially affects the breathing, and some are in this way more or less poisonous. Solid particles floating in the atmosphere may also produce disorders of respiration.

5. *Conditions affecting the apparatus concerned in the respiratory movements.*—These refer to the chest-walls and the diaphragm, and they include: (a) Certain painful affections, causing the patient voluntarily or involuntarily to limit or modify the movements, such as the early stage of pleurisy, pleurodynia, or peritonitis. (b) Spasm or paralysis of the muscles, from any cause. (c) Organic changes, as undue softness or rigidity of the thoracic walls, cancerous infiltration, muscular atrophy or fatty degeneration, or acute or chronic inflammation of the diaphragm.

6. *Obstruction involving the main air-passages.* This may be situated in the mouth, throat, nasal cavities, larynx, trachea, or primary bronchial divisions, and is due to a variety of causes, which cannot be discussed here further than to state that the obstruction may depend upon pressure from without; spasm or paralysis of the muscles of the larynx; some internal obstruction, whether from deposits, secretion, abscess (including also retropharyngeal abscess), foreign bodies, or new-

growths; or organic changes in the walls of the tubes, leading to their constriction.

7. *Physical conditions independent of the respiratory apparatus, but interfering with it in various ways.*—These may lie within the chest, as in the case of thoracic aneurysm, or a mediastinal solid tumour or abscess. They act by compressing the lungs or heart, obstructing tubes, affecting nerves, or interfering with the moving apparatus. Or the cause of the disorder may lie in the abdomen, such as excessive flatulence or tympanites, ascites, enlarged organs, ovarian tumours, or a pregnant uterus. They act mainly mechanically, by impairing the movements of the diaphragm. Breathing often becomes worse after food in cases in which it is difficult, in consequence of flatulent distension, especially when digestion is impaired.

8. *Conditions affecting the pleura.*—Any accumulation of air or fluid in one or both pleural sacs will necessarily tend to disturb respiration, as in pneumothorax, pleurisy, hydrothorax, or hæmothorax. It acts mechanically, and the degree of disorder will depend on the amount of the collection, the rapidity with which it takes place, the previous condition of the lungs, and other circumstances. Pleuritic adhesions also tend to embarrass respiration more or less seriously.

9. *Morbid conditions of the lungs.*—These have been left to the last, and it will be readily understood that all diseases of the lungs tend more or less to produce disorders of breathing. At the same time it must not be forgotten that these organs may be affected, even somewhat extensively, under certain conditions, without any obvious respiratory disturbance. Pulmonary diseases act in various ways, of which the most important are by affecting the circulation and the amount of blood in the lungs; by interfering with the entrance or exit of air through the bronchial tubes; by temporarily disabling or permanently destroying more or less of the pulmonary textures; or by influencing the respiratory act through its forces, and especially by the impairment or loss of the elasticity of the lungs required for expiration.

CLASSIFICATION.—The disturbance of breathing may be sudden, acute, or chronic; and its several forms may be included under three main divisions, namely: (1) **Deficient Respiration.** (2) **Dyspnœa or Difficulty of Breathing.** (3) **Peculiar Disorders.**

1. **Deficient Respiration.**—This comprehends the following varieties:—

(a) *Slow breathing.*—The frequency of the respirations may be notably reduced, without any other obvious disorder. Or this may be associated with marked shallowness of the movements, so that in extreme cases breathing seems to have almost entirely ceased, and can scarcely be recognised even by the most delicate tests. These deviations are observed in various conditions or diseases affecting the nervous system, such as hysteria, trance, shock or collapse, narcotic poisoning, and some cases of cerebral disease. They are accompanied by impairment or loss of consciousness, real or assumed, and by other varying symptoms. Sometimes the breathing is slow but deep, and may then be sighing, stertorous, or attended by flapping of the cheeks in expiration; this is noticed in apoplectic conditions. These disorders of breathing do not obviously disturb the patient.

(b) *Restrained breathing.*—By this is meant that the patient makes a voluntary and conscious effort to restrain or modify the act, because it produces or increases some painful or other morbid sensation. It may be obvious at once to the observer, or may only be revealed when the patient is made to take a deep inspiration. The respirations are often increased in frequency, but may be below the normal. The entire movements may be affected, or only those of either the chest or the abdomen, or even only of one side of the chest. The early stage of pleurisy, peritonitis, and angina pectoris afford examples of diseases causing this disorder of breathing.

(c) *Shallow and feeble breathing.*—The most striking feature in some conditions is the extreme feebleness and limitation of the act of respiration. This has already been alluded to, as noted in some cases of slow breathing, but the frequency is often much above the normal, and the class of cases now under consideration differ essentially from those previously mentioned. The disorder indicates gradual cessation of the respiratory functions and pulmonary action, becoming more and more obvious, and gradually terminating in death. Little or no air is changed, and at last the breathing becomes a mere ineffectual gasp. This form of disturbance is observed in persons slowly dying from various causes; in gradual filling of the air-tubes in fatal cases of bronchitis; and in cases of apoplexy or narcotism. It is often accompanied by rattling or gurgling râles, audible to the bystander, due to the presence of fluid in the air-passages, which become by degrees filled up. It may follow certain forms of dyspnœa.

(d) *Ineffectual breathing.*—The derangement thus named can only be recognised by making the patient attempt to draw a full breath. He may then be conscious of an inability to perform this act satisfactorily, or to expand the chest properly. What is more important, however, is that this impairment of the respiratory act is often evident on objective examination, when it is seen that in certain conditions the most powerful efforts to breathe produce little or no result, and the movements are obviously more or less ineffectual, either as a whole, unilaterally, or locally. This may arise from various causes, such as paralysis or spasm of the muscles, rigidity of the chest-walls, distension of the lungs in emphysema, pleuritic and other conditions interfering with their expansion, and certain morbid changes in these organs themselves. Ineffectual breathing is frequently associated with some form of dyspnœa.

2. **Dyspnœa or Difficulty of Breathing.**—Without making too marked a distinction between them, and remembering that they may be variously combined, there are certain forms of disordered breathing, usually characterised as *dyspnœa*, which deserve separate recognition.

(a) *Obstructive dyspnœa; Inspiratory dyspnœa.* This signifies that there is some obvious impediment or difficulty presented to the transmission of air through some part of the air-passages in respiration. The nature and severity of the disorder vary with the seat, cause, and degree of obstruction. Thus it may be that a swollen tongue, enlarged tonsils or other throat-condition, retro-pharyngeal abscess or some obstruction in the nose or naso-pharynx, blocks up the passage more or less completely, and the patient breathes with obvious difficulty; air

passing by the throat causes much noise, especially when the patient is asleep.

The most important form of obstructive dyspnoea, however, is that which is connected with the main air-tube, and it usually attracts immediate attention. It may be associated with the larynx or the trachea, or with both, and in the case of the larynx is liable to exacerbations. The gravity of the phenomena varies with the degree of obstruction, but they are more or less of the following kind. The patient is usually conscious of a difficulty in the passage of the air during respiration, referred to some spot, which may become very distressing; the act of breathing is usually more or less laboured, and this may culminate in a violent effort or struggle to breathe. The frequency of respiration is often below the normal, or at any rate it is but little increased, while the relative length of inspiration and expiration is disturbed. The difficulty may be experienced only during inspiration, or during both divisions of the act of breathing, but is usually most marked in inspiration, though occasionally during expiration. Various noises are produced by the passage of the air through the narrowed part, usually classed as *stridor*, the breathing being termed *stridulous*; and to an experienced and trained ear these become of great importance as indicating the existence and seat of obstruction. Signs of deficient aëration of the blood are very liable to accompany this form of dyspnoea; and in acute or sudden cases, or if the obstruction is very marked, there is danger of actual suffocation which may occur rapidly or even suddenly. Physical examination will indicate that air does not enter properly into the lungs, as evidenced especially by recession of the lower part of the chest during inspiration, particularly marked in children, in whom this form of dyspnoea is likely to lead to most serious consequences.

The obstruction may be situated lower down in the respiratory tract, either in one of the main bronchial divisions, or in the tubes distributed through the lungs, and then the character of the disorder merges in that of ordinary dyspnoea, except that it is likely to be attended by various noises, and that the physical signs of deficient entrance of air into one or both lungs are evident. When there are evident objective signs of deficient entrance of air into the lungs, the condition is termed *inspiratory dyspnoea*. This difficulty, however, may also depend upon weakness of the chest-walls, and of the inspiratory muscles, as in rickets.

(b) *Excessive breathing*.—*Ordinary dyspnoea*.—This is the disorder usually met with in various degrees, and it implies that respiration is carried on in excess. The act may be too frequent, or too powerful, or both, so that more than the ordinary amount of air is changed in a given time. The movements of the chest are more or less free under different circumstances. In severe cases the patient is obviously distressed, and the act of breathing is laboured, and may be noisy. Then the *alæ nasi* are seen to work; the patient cannot speak except in broken sentences, owing to want of breath; and there may be signs of apnoea. This form of dyspnoea is familiarly illustrated by the effects of undue exercise, such as running. Clinically it is associated in different degrees with numerous conditions, such as nervous disorders; fevers and other blood-conditions; many cardiac affections; conditions interfering with the action of the lungs,

such as pleuritic effusion or abdominal accumulations; and various diseases of these organs, impairing their functional activity, especially if acute, such as pneumonia or bronchitis.

(c) *Shortness of breath*.—While associated with other forms of dyspnoea, this disorder frequently exists alone in various degrees, and it may be of much consequence in drawing attention to disease of a serious character. Shortness of breath signifies that the breathing becomes more or less hurried, and the individual becomes conscious of dyspnoea, after making some effort which ordinarily does not cause any such effects, such as walking rather quickly or upstairs, singing, coughing, stripping, or even taking a few deep breaths in physical examination of the chest. When at rest he may feel perfectly comfortable, and breathing is quite natural, but it is easily disturbed in the ways above indicated. This disorder is observed in general debility; very markedly in pronounced anæmia; in many cardiac conditions, especially dilatation and degeneration; in pleuritic effusion frequently; and in many cases of chronic lung-disease, such as phthisis or emphysema.

(d) *Expiratory dyspnoea*.—In the form thus designated the difficulty is experienced during expiration, which becomes prolonged and laboured, in some cases extremely so, the extraordinary muscles of expiration being called fully into play. The relative lengths of inspiration, expiration, and the pauses are thus deranged, and inspiration may become extremely short, even a mere gasp. There is often a sense of discomfort or even distress, and this is liable in certain conditions to be increased by exertion, after taking food, or in certain postures. Expiratory dyspnoea may be a prominent feature in some cases of obstruction of the air-tubes; but is essentially connected with impairment of the expiratory elastic force of the lungs in cases of emphysema, and of the chest-walls when they are rigid, these two conditions often going together. These causes are frequently aided materially by blocking-up of the bronchi, as the result of bronchitis; or by spasmodic contraction of these tubes, in connection with asthma.

(e) *Orthopnoea*.—This is almost always combined with one or more of the other forms of dyspnoea, and the term indicates that the patient can only breathe at all, or at any rate with any degree of comfort, when the body is in a more or less upright posture. In some cases it is sufficient if he is propped up; in others he has to sit bolt upright in bed, or to bend forwards; in others still he is obliged to sit up altogether in some kind of chair, or even to stand, this being the only posture in which breathing can be carried on with any comfort. Cases of extensive cardiac disease, of acute pericardial and pleuritic effusion, of acute pneumonia, of asthma, and of aneurysmal or other thoracic tumours, afford illustrations of the causes of this disorder.

(f) *Paroxysmal dyspnoea*.—This may be of various kinds, but, as its designation implies, it signifies that the dyspnoea comes on mainly or entirely in fits or paroxysms. It is chiefly exemplified by paroxysms of laryngeal dyspnoea; by some cases of cardiac dyspnoea; and, above all, by fits of bronchial asthma. See ASTHMA, SPASMODIC.

3. *Peculiar Disorders*.—It is scarcely practicable to bring these under any definite subdivisions, and it will suffice to notice the very curious and

ten indescribable disorders of breathing observed in certain nervous cases; the interrupted, jerky, gasping, or yawning respiration which may be present in various conditions; and the peculiar disturbance generally known as *Cheyne-Stokes respiration*, but also termed *rhythmic dyspnoea*. This is rare, but may occur in connection with certain cardiac diseases, especially fatty degeneration; Bright's disease; injury to the brain; and cerebral hæmorrhage, or other brain-lesions. It is characterised by the breathing at intervals becoming by degrees more and more rapid and deep up to a certain point; and then subsiding in the same gradual manner, until finally there is a complete cessation of respiration, with a dead silence, the pause lasting a variable time, and then the same series of phenomena being repeated.

EFFECTS.—Many of the disorders of breathing which have now been considered are not attended by any obvious effects, and are practically of little or no consequence. Moreover, it must be noted that patients may become so accustomed even to marked derangements of the function of respiration, that they are not conscious of any injurious results therefrom. Most individuals under such circumstances, however, are conscious of more or less discomfort or other sensations, referable to some part of the respiratory apparatus. These are very unreliable and vague in their meaning; but there are defects which give important information in many cases, and which depend either upon the want of due aëration of the blood, or upon the interference with the general venous circulation which disorders of breathing so frequently induce. These will vary, not only with the nature of the disorder, but also with its degree, and the rapidity with which it is set up. Thus there may be actual suffocation, sudden or rapid, or a condition approaching more or less that of asphyxia or apnoea (*see ASPHYXIA*). Or a chronic state of venous congestion and venosity of the blood may be set up, indicated by a tendency to cyanosis, with enlargement of the visible superficial capillaries; general chilliness and coldness of the extremities; mental apathy or dulness, with headache and other signs of morbid blood-supply to the brain; general languor, laziness, and muscular weakness; dyspeptic disorders; changes in the urine; and other well-known phenomena. In cases where the respiratory functions are chronically affected in children and young persons, in such a way that the blood is never properly aërated, growth and development are markedly impeded. Patients suffering thus may present a peculiarly stunted appearance. The features tend to become permanently thick and coarse; and the ends of the fingers and toes often become clubbed. In certain forms of dyspnoea the fat of the body tends to disappear; while the muscles of respiration not uncommonly become hypertrophied from excessive use.

TREATMENT.—The indications to be fulfilled in treating disorders of respiration, and the measures by which these are to be carried out, must obviously present considerable variety in different cases; and it will only be practicable here to offer a few general hints on the subject. In the first place, no treatment whatever may be called for in some instances; while in other cases nothing can be of any service. The primary indication should always be to attend to the cause of the disorder, and by curing, removing, or alleviating this, the disturbance

may often be got rid of or materially diminished. This may be illustrated by treatment directed to laryngeal obstruction, anæmia, pleuritic pain or effusion, bronchitis, or cardiac derangement. By improving the condition of the blood when anæmia is present, breathing is frequently much improved, even when actual disease exists which disturbs it, such as phthisis or cardiac mischief. Attention to the condition of the air inhaled is in some cases of much importance, as regards its purity, temperature, degree of moisture, pressure, and other points. It must be remembered that some forms of dyspnoea actually require an atmosphere which contains an abnormal proportion of carbonic acid. Great advantage frequently results from giving proper instructions to patients as regards posture, avoidance of exertion, diet, the act of coughing, or even the act of breathing itself. This is especially important in certain forms of paroxysmal dyspnoea; and any cause which is known to produce any such attack should be carefully avoided. Moreover, the patient may sometimes be materially assisted in the act of breathing by mechanical means. Not uncommonly active measures are called for, for the purpose of relieving some more or less urgent form of dyspnoea. For this purpose various means are indicated in different cases, such as venesection, or local removal of blood from the surface of the chest; dry-cupping over this region; the internal administration of antispasmodics, stimulants, pulmonary sedatives, or other appropriate agents; inhalations of different kinds, in the form of gas, vapour, or smoke; subcutaneous injections of morphine or other active drugs; or the application to the chest of sinapisms, hot poultices, fomentations, or turpentine stupes. Treatment directed to the asphyxial condition may be urgently demanded, especially artificial respiration (*see ASPHYXIA*); and operative procedures, such as laryngotomy or tracheotomy, or intubation, may be called for in cases where the main air-tube is obstructed. In chronic cases, where the respiratory functions are imperfectly carried on, the conditions resulting therefrom must be remembered, and as far as possible obviated. Warm clothing is essential under such circumstances; and, if practicable, a residence in a genial and warm climate is often of the greatest practical service.

FREDERICK T. ROBERTS.

RESPIRATORY MURMUR.—The sound heard on auscultation over the lungs in respiration. *See PHYSICAL EXAMINATION.*

REST, Therapeutics of.—In considering rest as a therapeutic agent it is requisite to understand its nature, its varieties, the indications for its use, and the ways of employing it. There are two chief varieties: (1) Rest of the *body and brain generally*; and (2) local rest of a *diseased organ or inflamed part*.

1. *Rest of the body and brain generally.*—*See NEURASTHENIA; PHTHISIS; and PERSONAL HEALTH.*

2. *Local rest.*—This, which may be called *mechanical rest*, is well known to every surgeon to be an agent of supreme value in the treatment of wounds, fractures, displacements, or inflammation of joints; as it is obvious that every movement to which a wounded or inflamed part is subjected must act on the one hand like a repetition of the original injury, and on the other hand like a

continuance of the irritating cause. Thus rest is not only a negative advantage, as saving the patient from renewed injury or irritation, but a positive remedy, as it diminishes the heat of the body, reduces the pulse, and alleviates pain. Rest is of so much value in the treatment of inflammation, that in some instances no means will advance the cure without it, and numerous injuries of the body, external or internal, would do well with perfect local rest and nothing else.

It was on this principle that Pott treated all fractures of the extremities, by placing the limbs in a position of easy flexion, so that the muscles which had been thrown into spasm by the fracture were relaxed.

APPLICATION.—The application of rest in diseased conditions of the different parts of the body is so varied, and the cases in which it should be employed are so numerous, that it would be impossible to enumerate them all. In surgical practice and in the treatment of diseases of the eye, rest in one or all its varieties is the daily routine. In this article we shall only deal with its employment in medical practice, and shall select a few examples out of many to illustrate its benefit in different regions of the body.

A. Diseases of the Respiratory Organs.—

The objects of the treatment by rest may be stated to be (Roberts): (1) To maintain structures which are actually diseased, or in danger of becoming so, in as quiescent a state as possible; in short, to try to produce mechanical rest, as is ordinarily done in the case of a diseased joint. (2) To check or limit the entrance of irritating gases—be they noxious, or simply of a different degree of temperature or humidity from that of the internal part with which the air comes in contact. (3) To quiet the circulation through the organs which are being placed in a condition suitable for repair.

1. *Acute inflammation of the larynx and bronchi.*

The patient is to be placed in an equable and moderately high temperature, and the atmosphere impregnated with moisture; all speaking or using the voice must be forbidden, while the patient's wants may be made known by means of a slate and pencil (Hilton).

In addition to *general rest*, *physiological rest* is obtained by remedies to relieve the congested right heart, and to remove the mucus which is causing the symptoms of asphyxia. Here relief is attainable by restraining on the one hand the outpouring of mucus into the small tubes of the lung, and getting rid of that which is already poured out, by means of alkaline and stimulating expectorants; and by maintaining, on the other hand, the forces of the circulation, and relieving the overloaded right heart, by mercurial and hydragogue cathartics, diuretics, and diaphoretics.

2. *Pleurisy.*—In addition to keeping the patient quiet, restraining breathing, and forbidding conversation, the most effectual way of employing rest to the inflamed surfaces of the serous membrane is by mechanically fixing the side with adhesive plaster, as we should do for an inflamed joint. The forms of pleuritis to which this is most applicable are: Acute general pleurisy, seen early; dry pleurisy of a small area; that accompanying pneumonia, the result of a fractured rib; and in the advanced stages of phthisis pulmonalis with breaking down of lung-tissue, and where fits of coughing and pain are produced by stretching of the bands of organised lymph

which bind the costal and visceral layers together. The plan proposed by F. T. Roberts, and which has answered remarkably well in the hands of the writer, is as follows: Apply two or three layers of plaster, cut in strips of about four inches, thus: the first strip is laid on obliquely in the direction of the ribs, the second across the course of the ribs, the third in the direction of the first, the fourth as the second, and so on until the entire side is covered. A strip is also passed over the shoulder, which is kept down by another fixed round the side across its ends. Each strip should be long enough to extend from the spine to the sternum.

3. *Hæmoptysis.*—Rest is the most important of all measures in the treatment of hæmoptysis; rest of the body, the chest and lungs, and of the mind. The patient must be kept in bed, forbidden to use his voice, told to avoid coughing; and he should be given at once $\frac{1}{4}$ gr. or $\frac{1}{2}$ gr. of morphine hypodermically. All other drugs are quite secondary to this treatment by rest, and under it alone bleeding will cease. See HÆMOPTYSIS, p. 621; and PHTHISIS, p. 1228.

B. Diseases of the Heart and Blood-vessels.—

1. *Pericarditis.*—The mode of applying rest in this disease must necessarily be different from that which obtains in pleurisy, as actual arrest or even limitation, to any degree, of the heart's action—which theoretically and by analogy might be expected to be followed by the best results—would of course be out of the question. Rest must therefore be differently attained, by general rest and quiet, and by physiological medication. The advantages of perfect rest in the horizontal position are evident, as by it the action of the heart is rendered slower, and the attrition of the inflamed surfaces against each other is lessened by some 17,280 beats in the twenty-four hours, and thereby the tendency to effusion diminished, and resolution encouraged. The medicine above all others to produce physiological quiet is opium. When not otherwise contra-indicated, and when carefully watched, it is to be used freely, in grain-doses every second or third hour, as it is remarkably little liable to produce narcotism.

2. *Thoracic aneurysm.*—To Tufnell of Dublin is due the credit of having arranged, according to Valsalva's theory, a routine treatment based on the principle of securing the most perfect rest attainable. Tufnell's method may shortly be stated to be as follows: The patient is to be placed in a bright airy room on a prepared bed or couch, on which he must be contented to remain for eight or ten weeks. He must thus lie in the horizontal position, and not even for a moment assume the erect posture. Accordingly, the bed must be so constructed that the requirements of nature can be attended to without alteration of position. The diet is to be restricted to a minimum of solids and fluids. The patient's mind is to be freed from all anxiety, and pain and sleeplessness relieved by opium. The object of these means is to give rest to the aneurysm (1) by reducing the absolute quantity of blood circulating, without taking any of its ingredients from it by bleeding; (2) by rendering the blood hyperinotic; (3) by diminishing the rate and force of the current through the sac. The horizontal position in a healthy individual makes a difference of at least twelve cardiac beats a minute less than the erect position, and in aneurysm this difference amounts to twenty or even forty beats.

Taking it at the lowest rate of difference, it is evident that in the horizontal position the pulse-wave passes 17,280 times less through the body in the twenty-four hours. The aneurysmal sac is proportionately less often distended, and the threatened breach in the wall of the artery is averted by layers of fibrin being deposited by the more slowly moving and concentrated stream.

C. Diseases of the Abdominal Viscera.—In the therapeutic consideration of disease of these organs the principle of rest is not less plainly indicated than in the other parts of the body we have discussed; and by neglect of so simple and yet so potent an agent all other treatment may significantly fail to relieve or to cure.

1. In *acute inflammation of the stomach and in ulcer*, rest may be secured by strict diet, or in some cases by temporary total deprivation of food, enemas supplying the requisite nourishment. Local rest can best be obtained by the physiological action of opium upon the vermicular movements of the intestines, and by avoiding all irritants or purgatives. Opium by the mouth, or morphine hypodermically, may be required in full doses, so as to arrest all peristalsis; and thus an inflamed or ulcerated surface is placed at rest, and nature is enabled to prevent perforation, and cure the disease. It cannot be too strongly stated that the injudicious employment of purgatives in threatened perforation or peritonitis, is not only unscientific, but the worst possible practice, as it is almost sure to result in the death of the patient.

2. *Inflammation of the kidneys.*—As the skin and bowels may vicariously perform many of the excretory functions of the kidney, the first indication in *acute nephritis* is to relieve and rest that organ, by general rest in bed, local depletion, by calling rigorously upon the skin and intestines, and by withholding all nitrogenous foods and stimulating diuretics.

J. MAGEE FINNY.

RESUSCITATION (*re-*, again; and *suscito*, I arouse).—**DEFINITION.**—The recovery from suspended animation or apparent death. In these conditions, of course, all signs of circulation and respiration have apparently disappeared, but usually the failure of respiration has preceded that of the circulation, hence it is always advisable to attempt resuscitation, however hopeless the case may appear, provided unmistakable signs of death are not present. For the purposes of treatment we may classify as (A) *syncope* those cases where the lips and mucous membrane are found pale and exsanguine; and as (B) *asphyxia* those where cyanosis is marked.

A. Syncope.—Syncope may arise (1) from mental emotion, sudden pain, or shock; (2) from drugs and poisons, including anæsthetics, especially chloroform; (3) from hæmorrhage, or anything which reduces the due supply of blood to the heart; and (4) from fatty degeneration or dilatation of that organ.

TREATMENT.—Place the patient immediately on the floor, turn him on to his right side, with the pelvis and feet raised. Nélaton has urged complete inversion of the body. This is extremely useful, and can be readily performed with infants and children; but in the case of adults the whole of the weight of the intestines and omentum would be thrown on the diaphragm, and by greatly impeding its free action this method might be injurious. The

windows of the room should be opened; the face fanned; cold water dashed on the face and chest; and smelling salts held to the nostrils. If natural breathing has not returned, one or two compressions of the chest will in all probability re-establish it, but if not, Howard's method of artificial respiration should be commenced: *Position of patient.*—Face upwards; a hard roll of clothing beneath thorax, with shoulders slightly declining over it. Head and neck bent back to the utmost. Hands on top of head. Strip clothing from waist and neck. *Position of operator.*—Kneel astride patient's hips; place your hands upon his chest, so that the ball of each thumb and little finger rest upon the inner margin of the free border of the costal cartilages, the tip of each thumb near or upon the xiphoid cartilage, the fingers dipping into the corresponding intercostal spaces. Fix your elbows firmly, making them one with your hips. *Action of operator.*—Pressing upwards and inwards towards the diaphragm, use your knees as a pivot, and throw your weight slowly forwards for two or three seconds until your face almost touches that of your patient, ending with a sharp push which helps to jerk you back to your erect kneeling position. Rest three seconds; then repeat this movement as before, continuing it at the rate of seven to ten times a minute; taking the utmost care, on the occurrence of a natural gasp, to gently aid and deepen it into a longer breath, until natural breathing returns.

This method is said to keep the passage through the larynx free without the aid of an assistant or any contrivance for the purpose, and is recommended for that reason. Artificial respiration must precede the use of the stomach-pump, and be continued until either the pulse or natural respiration returns; but should the stomach-contents be evacuated, then the subject must be turned quickly on his side and the mouth cleared before continuing artificial respiration. Keep up the temperature of the body by hot blankets or hot bottles. Stimulating the heart by galvanism has been recommended, but it is a doubtful remedy. It is not easy to make it produce general and effective contraction, such as would cause the blood to move forward, and, failing to do this, it probably does harm by exhausting the irritability of those parts which it does excite. Ammonia, or nitrite of amyl, may be held to the nostrils. A little brandy and hot water, eau-de-Cologne and water, wine, or other stimulant, as sulphuric ether or sal volatile, is now to be given, with care that none of it enters the trachea. If swallowing is impracticable, inject warm fluids into the rectum. In cases of syncope from loss of blood, infusion of saline solution may be required. See SALINE SOLUTION.

B. Asphyxia.—(a) *Asphyxia neonatorum.*—The mouth and nostrils of the infant should be wiped dry, clearing away all mucus, amniotic fluid or meconium, and the body freely exposed, while the head is allowed to fall back over the hand which supports the nape. One or two compressions of the thorax are then generally sufficient to establish breathing. Failing relief, an effort should be made to arouse the reflexes by plunging the trunk into cold water and water at 100° alternately, a gasping inspiration in nearly all cases occurring during the cold immersion. These immersions may be continued till the child cries vigorously. In the event of a child being born

pale and flaccid, like a corpse, Schultze recommends the cord being immediately ligatured, the mouth cleared, and artificial respiration commenced. Any previous attempt to arouse reflexes he considers as valuable time lost. Sylvester's method, and the 'swinging method' of Schultze, are the best forms of artificial respiration. In mouth-to-mouth insufflation the risk of rupturing the lungs, dilating the stomach, and tubercular or other infection should not be overlooked. Marshall Hall's and Howard's methods may be used after the first inspiration has occurred, or together with mouth-to-mouth insufflation (see ARTIFICIAL RESPIRATION). Experiments made by Dr. Champneys show that Hall's and Howard's methods of artificial respiration are absolutely useless as a means of directly inflating the lungs of still-born children; and also that Sylvester's method, and its modification by Bain and Pacini, introduce more air than any other method.

(b) *Asphyxia from breathing noxious gases.*—The body should be brought into fresh air, and all clothing loosened; artificial respiration at once commenced, while an assistant should devote his attention to keeping the air-way free; and hot blankets and hot-water bottles applied. Venesection is useful if there be much venous engorgement, and inhalation of oxygen when obtainable. Efforts should be persisted in so long as any cardiac action can be detected.

(c) *Asphyxia from mechanical obstruction of the air-passages.*—The cause of obstruction must be removed, if possible by adopting the inverted position of Howard's method. Coins or plum-stones may thus dislodge themselves. In the absence of forceps, a button-hook or the handle of a table-spoon may be useful, especially in the removal of a lump of hard food. Laryngotomy or tracheotomy must be performed the instant the pulse becomes imperceptible at the wrist.

(d) *Asphyxia from poisons or anæsthetics.*—In the asphyxia of advancing coma from narcotics and anæsthetics, the breathing may stop from failure of the centres in the medulla presiding over circulation and respiration. In this case artificial respiration, by simply compressing the chest at intervals of five seconds, may suffice, but very often there is also the mechanical obstruction in the larynx to be considered. If drawing forward the tongue, raising the chin and throwing the head back do not effect a free passage of air, Howard's or some other method of artificial respiration should be commenced (see ARTIFICIAL RESPIRATION). It is well to understand that when the muscles of the larynx are paralysed, the glottis becomes valvular in action, or partially so—that is to say, it permits air to pass outward freely, but only a weak current of air to pass inward. A strong current brings the sides together, and gives rise to complete obstruction. This is chiefly caused by the drawing together of the relaxed arytaeno-epiglottidean folds of mucous membrane; and in order to obviate this kind of obstruction, the folds should be tightened, by throwing back the head and raising the chin as far as possible away from the sternum. This position frequently renders it unnecessary to catch hold of the tongue with artery forceps, the treatment usually recommended.

(e) *Asphyxia from drowning.*—In asphyxia from immersion in water there are two serious complications, namely, first, the presence of water and mud in

the air-passages, and, secondly, the depressing effect of cold. With the view of more effectually removing the water from the air-tubes, Howard gives the following rules: *Position of patient.*—Face downwards. A hard roll of clothing beneath the epigastrium, making that the highest point, the mouth the lowest. Forehead resting on forearm or wrist keeping mouth from ground. *Position and action of operator.*—Place left hand, well-spread, upon the base of the thorax to the left of the spine; the right hand upon the spine, a little below the left. Throw upon them, with a forward motion, all the weight and force the age and sex of the patient will justify, ending this pressure of two or three seconds by a sharp push, which helps you back again into the upright position. Repeat this two or three times, according to the duration of the immersion, and then resort to the method described in the treatment of syncope.

The following rules have been published by the Royal Humane Society. They recommend the Sylvester method, but probably this and the modification by Bain, in which the anterior fold of the axilla on both sides is grasped with the clavicle and pulled upwards, are less useful than the Howard plan, which favours the patency of the air-passages.

DIRECTIONS FOR RESTORING THE APPARENTLY DEAD:—

1. *If from Drowning or other Suffocation, or Narcotic Poisoning.*—Send immediately for medical assistance, blankets, and dry clothing, but proceed to treat the patient *instantly*.

The points to be aimed at are—first and immediately, the restoration of breathing; and secondly, after breathing is restored, the promotion of warmth and circulation.

The efforts to restore life must be persevered in until the arrival of medical assistance, or until the pulse and breathing have ceased for at least an hour.

Treatment to Restore Natural Breathing.

Rule 1.—*To adjust the patient's position.*—Place the patient on his back on a flat surface, inclined a little from the feet upwards; raise and support the head and shoulders on a small firm cushion or folded article of dress placed under the shoulder-blades. Remove all tight clothing about the neck and chest.

Rule 2.—*To maintain a free entrance of air into the windpipe.*—Cleanse the mouth and nostrils; open the mouth; draw forward the patient's tongue and keep it forward; an elastic band over the tongue and under the chin will answer this purpose.

Rule 3. *To imitate the movements of breathing.* Firstly, to induce inspiration, place yourself at the head of the patient, grasp his arms, raise them upwards by the sides of his head, stretch them steadily but gently upwards, for two seconds. By this means fresh air is drawn into the lungs by raising the ribs.

Secondly, to induce expiration, immediately turn down the patient's arms, and press them—or your own hands—gently against the sides of his chest, for two seconds. By this means foul air is expelled from the lungs by depressing the ribs.

Repeat these measures alternately, deliberately, and perseveringly, fifteen times in a minute, until a spontaneous effort to respire is perceived. When a spontaneous effort to respire is perceived cease to

mitate the movements of breathing, and proceed to induce circulation and warmth.

Rule 4.—*To excite inspiration.*—During the employment of the above method excite the nostrils with snuff or smelling-salts, or tickle the throat with a feather. Rub the chest and face briskly, and dash cold and hot water alternately on them. Friction of the limbs and body with dry flannel or cloths should be had recourse to. When there is proof of returning respiration the individual may be placed in a warm bath, the movements of the arms above described being continued until respiration is fully restored. Raise the body in twenty seconds to a sitting position, dash cold water against the chest and face, and pass ammonia under the nose. Should a galvanic apparatus be at hand, apply the sponges to the region of diaphragm and heart.

Treatment after Natural Breathing has been Restored.—*To induce circulation and warmth.*—Wrap the patient in dry blankets, and rub the limbs upwards energetically. Promote the warmth of the body by hot flannels, bottles, or bladders of hot water, heated bricks to the pit of the stomach, the armpits, and the soles of the feet. On the restoration of life, when the power of swallowing has returned, a teaspoonful of warm water, small quantities of wine, warm brandy and water, or coffee should be given. The patient should be kept in bed, and a disposition to sleep encouraged. During reaction large mustard poultices to the chest and below the shoulders will greatly relieve the distressed breathing. In all cases of prolonged immersion in cold water, when the breathing continues, a warm bath should be employed to restore the temperature.

2. **If from Intense Cold.**—Rub the body with snow, ice, or cold water. Restore warmth by slow degrees. It is dangerous to apply heat too early.

3. **If from Intoxication.**—Lay the individual on his side on a bed with his head raised. The patient should be induced to vomit. Stimulants should be avoided.

4. **If from Apoplexy or Sunstroke.**—Cold should be applied to the head, which should be kept raised; clothing removed from neck and chest; and stimulants avoided.

How soon should alcoholic stimulants be given? Certainly not until natural respiration has been induced; and, in cases of narcotic poisoning, not until consciousness has been restored. If, on the return of consciousness, the patient is in pain, or faint, the inhalation of a few drops of ether or smelling ammonia is indicated. In the absence of these a few teaspoonfuls of brandy may be given. Hot tea and coffee should be the first refreshment swallowed, and in general it should not be pressed upon the patient, as vomiting is more exhausting than waiting a few hours for food.

J. T. CLOVER.
CARTER BRAINE.

RETCHING (A.-S. *hræcan*).—An ineffectual effort at vomiting, sometimes accompanied by the expulsion of gas from the stomach. *See* VOMITING.

RETENTION OF URINE.—*See* MICTURITION, Disorders of.

RETINITIS.—Inflammation of the retina. *See* EYE, AND ITS APPENDAGES, Diseases of.

RETRACTED ABDOMEN.—The abdomen as a whole presents under certain circumstances more or less depression of its anterior wall, when it is said to be *retracted*, and this may reach such a degree that the region becomes 'boat-shaped,' and its anterior boundary sometimes seems almost to come into contact with the spinal column behind. The bony prominences of the crest and interior angles of the ilium, the pubes, Poupart's ligament, and the lower margin of the chest often stand out prominently. In some instances the retraction is partial, involving the lower part of the abdomen, while the upper part is distended.

A retracted abdomen frequently renders it more easy to investigate by physical examination the contents of this cavity; and it must be remembered that the condition may be associated with diseases of abdominal organs, which can then be readily detected, or even with abdominal tumours. It may, however, also itself give information of importance in diagnosis. The chief conditions under which a retracted abdomen may be met with, so as to be of clinical importance, are as follows: (1) In certain cases of disease of the brain or its membranes, and especially acute tubercular meningitis. (2) In some forms of intestinal colic, particularly that form associated with lead-poisoning—the so-called *painter's colic*. (3) As a part of marked general emaciation from any cause, but especially that due to starvation, or to chronic diarrhœa from intestinal ulceration and other conditions. (4) In connection with chronic diseases of the œsophagus, stomach, intestine, or pancreas, causing obstruction in some part of the alimentary canal, so that food cannot be taken in, or is prevented from passing along the tube. Here the retraction is also partly due to the general emaciation. (5) As one of the consequences of chronic peritonitis. It will be seen from a consideration of the causes just mentioned, that retraction of the abdomen immediately results either from a spasmodic contraction of the intestines and abdominal muscles; general wasting; absence of food from and contraction of the alimentary canal; or peritoneal adhesions. It may be mentioned that marked temporary retraction of the abdomen is sometimes noticed in connection with the act of breathing, in consequence of disordered action of the diaphragm. *See* DIAPHRAGM, Diseases of.

FREDERICK T. ROBERTS.

RETRACTED CHEST.—*See* DEFORMITIES OF THE CHEST.

RETROCEDENT (*retro*, back; and *cedo*, I go).—A term employed in connection with certain acute diseases, when their prominent external manifestations disappear or, as it were, go back. Retrocession is often associated with the simultaneous occurrence of internal disturbance. The term is often applied to phenomena observed in gout, rheumatism, certain skin-diseases, and the eruptive fevers.

RETROFLEXION (*retro*, back; and *flecto*, I bend).—A form of displacement in which an organ is bent backwards upon itself. *See* UTERUS, Diseases of.

RETRO-PHARYNGEAL ABSCESS.—*See* PHARYNX, Diseases of.

RETROVERSION (*retro*, back; and *verto*, I turn).—A form of displacement in which an organ is turned back but not bent. See UTERUS, Diseases of.

RE-VACCINATION.—The operation of repeated vaccination. See VACCINATION.

RHABDITIS NIELLYI.—An immature parasitic nematode, found in the skin in one or more instances of cutaneous disease, characterised by intense itching and the formation of papules and vesicles.

RHABDONEMA INTESTINALE (*βάβδος*, a rod; *vḗua*, a thread).—A genus of small parasitic nematodes found in the stools in certain cases of diarrhoea (p. 463).

RHEINFELDEN, in Switzerland. — See MINERAL WATERS.

RHEUMATIC FEVER.—A popular synonym for acute rheumatism. See RHEUMATISM, ACUTE.

RHEUMATIC GOUT.—A popular name for several kinds of chronic joint-disease, especially rheumatoid arthritis and chronic rheumatism.

RHEUMATISM, Acute (*ῥευμα*, a fluxion).—**SYNON.** : Rheumatic Fever; Fr. *Rhumatisme Articulaire Aigu*; Ger. *Acuter Gelenkrheumatismus*.

DEFINITION.—An acute disease; caused by certain infective, diathetic or climatic influences; and characterised by fever, sweats, acute shifting inflammatory and other nutritional changes in connection with the joints and related structures, and certain of the viscera, particularly the heart, as well as the serous membranes.

ÆTIOLOGY.—The *efficient* cause of acute rheumatism is unknown. Different micro-organisms have been described in connection with it, but an ætiological relation between any one of them and the disease is not established. Of the *predisposing circumstances* the most important is inheritance, which can be traced in 27 per cent. of all cases ('rheumatic diathesis'). The great majority of first attacks occur in persons under the age of thirty; and the larger proportion of these between the ages of sixteen and twenty-five. At the same time, rheumatism is by no means uncommon either in children or in persons past middle life. Rather more males than females suffer; but the influence of sex is inconsiderable apart from other circumstances. Indeed, when all the varieties of the disease are included, it is more common in girls than in boys, particularly between the ages of ten and fifteen. Occupation and social position are possible predisposing conditions. Laborious outdoor occupations in which persons are exposed to chills, poverty, and the many evils associated with these, are believed to contribute the largest percentage of cases.

The most common *determining circumstance* of acute rheumatism is exposure to cold and wet, or exposure to cold after severe exertion (see PERSONAL HEALTH, p. 1205). In London it is most frequent during the months of October and November. Rheumatism may suddenly make its appearance after a sprain or other injury to a joint, which may also determine the distribution of the disease in the articulations. Similarly, the order of invasion of the several joints is due in some instances to the amount of exercise to which they

have been respectively subjected. An attack of acute rheumatism is occasionally referred to derangement of digestion and of the functions of the liver, especially in subjects who have previously suffered. Indulgence in abundant, rich or indigestible food will certainly determine a relapse in persons convalescing from the disease, and may possibly induce an attack in the predisposed. Bodily exhaustion or depressing mental influences, and acute diseases of other kinds, such as scarlet fever, erysipelas and influenza, may excite rheumatism under similar circumstances. Exhaustion by lactation or by chronic uterine disease, tedious convalescence, the puerperal state and possibly simple despondency may also act in this way in different instances. Certain regions or districts, parts of districts, or even houses, appear to deserve the name of 'rheumatic,' from the number of residents who suffer from the disease, and from the probability that a person, otherwise predisposed to rheumatism, will be more likely to be attacked if he enter such an area.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances in acute articular rheumatism are negative on the whole, not so much in consequence of the absence of morbid changes in the affected parts, as from the slight degree to which these changes have advanced. On opening an affected joint, we find moderate hyperæmia, occasionally with ecchymosis, of the synovial membrane and fibrous tissues connected with the articulation. The synovial surfaces present a somewhat opaque, granular swollen appearance. A considerable amount of inflammatory effusion occupies the articular cavity. This is generally a thin, clear, alkaline, albuminous fluid; occasionally it is turbid, with flakes of fibrin and cell-products; rarely it is purulent. The cartilages connected with the joint probably share in the inflammatory changes, especially if the process be severe; and the associated soft parts, including the tendons and their sheaths, are very frequently hyperæmic and the seat of effusion. In the subcutaneous structures in young subjects there may be found, over the articular ends of the bones and connected with the fasciæ and with tendon-sheaths, small nodules of fibroid tissue of a translucent appearance. These present the microscopical characters of rapidly growing connective tissue.

The non-articular lesions are far more important. Of these the most frequent are inflammation of the cardiac valves, myocardium and pericardium, and congestion or inflammation of the lungs. Inflammation of the pleura is less commonly found; in rarer instances inflammation of the peritoneum, bronchi, larynx, meninges, testes and renal tubules. When pyrexia has been high, the solid viscera, including the heart, present granular degeneration and are prone to rapid decomposition; and in cases of hyperpyrexia the blood is fluid. The blood has frequently been subjected to chemical analysis, but without any positive result of a pathological kind. The reaction of the liquor sanguinis is alkaline, as in health. The fibrin is said to increase in amount to 1 per cent. instead of .25 per cent. (p. 159). The amount of urea is not above the normal (p. 160). Neither excess of uric acid, lactic acid nor any other abnormal principle has been found in the blood during an attack of acute rheumatism. The presence of micrococci, zoogloea-masses and bacilli in the blood and serum has been described, but not substantiated. The leucocytes are increased. The red

puscles rapidly diminish in numbers, as well as their hæmoglobin-value, during the acute stage, and are rapidly restored during convalescence.

SYMPTOMS.—After suffering for a time from aching pains in the limbs and trunk, flying pains and stiffness in the joints, malaise, chilliness and sore-throat, the subject of acute rheumatism is seized with severe pain in one or more of his joints, experiences a chill or slight rigor, and is found to have several degrees of fever. The local and general symptoms quickly develop; and a striking picture is presented by the patient. He lies motionless in bed, flat on his back, with every joint at rest and carefully guarded. The neck, back and legs are straight; the arms folded across the body, or extended along either side; the eyes are closed, and the patient is approached as he approaches the bedside. The face is found bedewed with perspiration; and the rest of the body is profusely covered with sweat, which gives off a strong acrid odour. The countenance is full, heavy, and expressive of a subdued feeling of pain and anxiety of movement; the complexion may be of a dirty sallow colour, or even slightly jaundiced; the cheeks are probably flushed. The affected joints are found to be swollen and red, hot to the touch, remarkably tender, and the seat of pain, which varies much in character and intensity. One joint, or several, or nearly every joint in the body, may be found in the condition just described. Peculiar firm nodules are observed to form in connection with the joints and other osseous and fibrous structures. The patient also complains of a feeling of illness, thirst and anorexia; the tongue is foul and creamy; the throat may be somewhat sore, and the bowels are irregular. The pulse is frequent, soft even to diastole, and rather large. Respiration is somewhat accelerated, and there may be slight cough. The urine is scanty, high-coloured, very acid, and loaded with lithates. The skin is covered with perspiration, congested and warm; and probably presents sudamina or miliaria in places. The patient's mind is perfectly clear, and his attention appears to be chiefly directed to the maintenance of the affected joints in the most easy position possible. Until successful in this endeavour he is distressed and miserable; and even if he have obtained temporary relief and have gone to sleep, he is liable to be suddenly aroused by involuntary spasms of the muscles connected with the affected joints. The pain is so severe when the disease is at its height that sleep cannot be obtained. Meanwhile symptoms and signs of invasion of the heart and pericardium, of the lungs and pleura, or of other of the viscera individually or in various combinations, often make their appearance, as well as erythema, chorea, or rarer rheumatic manifestations and a variety of complications.

For a period, which would appear to be perfectly indefinite, the patient continues in this condition, which varies considerably in intensity from day to day. But while it thus persists, the remarkable and characteristic fact is observed in this disease, that the arthritic phenomena are at once transient and erratic; that is, that the rheumatism passes rapidly from joint to joint, the joints which were affected the one day being nearly well the next, and a fresh series swollen and painful, while the non-articular phenomena may be equally evanescent and changeable. In this manner most of the

joints of the limbs may have been affected in the course of a week, and the number of joints simultaneously affected is very variable. Thereafter the disease may make a further invasion of joints previously involved, and that repeatedly; and the other symptoms and signs vary still.

At last the rheumatism appears to have exhausted itself: no fresh joint is attacked; and the parts last affected lose more or less completely the final traces, both objective and subjective, of the severe process which they have undergone. The patient now assumes a less constrained posture; the other symptoms decline; the perspirations disappear; the countenance becomes more bright; spirits and strength return; the tongue cleans, and the appetite is rapidly restored. If the heart or other of the viscera have escaped, the pulse falls in frequency; the urine is passed in greater quantity, is less acid, and no longer deposits urates; and the temperature falls to the normal. The joints remain for some time, however, stiff, weak, and painful on movement. Relapse is not uncommon at this stage, or a little later. Anæmia and debility are almost constant sequelæ, and in a considerable number of instances the heart is left permanently damaged.

Analysis of Clinical Phenomena.—*Invasion.*—In the great majority of cases the patient gradually 'sickens for' acute rheumatism for several days before the symptoms are fully declared. He feels ill and out of sorts, chilly, indisposed to eat or work; sleeps badly; complains of sore-throat, aching pains in the limbs, and shooting, shifting pains in the joints; and presents a sallow, patchy complexion, and a dull, heavy, yellowish appearance of the eyes. Altogether, the condition of the patient is very much that of the subject of a severe catarrh; the tongue, digestion, bowels, urine and pulse presenting the ordinary characters of moderate fever. On careful examination it is found that the pains are of two kinds. The first kind are by far the more severe, and consist of severe muscular aching in various parts of the limbs and trunk; while the second kind are of the nature of flying pains in the joints or associated parts. The muscular aching appears to be similar to or even identical with the 'break-bone' pains which are familiar in influenza, and in the invasion-stage of some eruptive fevers. They are, therefore, not characteristic. The flying pains, which are, however, not always present—especially in first attacks—are actually situated in the articulations, for instance, the ankles, knees or wrists, and are of the nature of sharp twinges, suddenly leaving one joint to return as quickly in another. Towards the end of the stage of invasion these pains become less 'shifting;' and when, as the patient will say, they have 'settled' in one or more joints, the rheumatism has passed into the second stage, that of the declared disease. Stiffness of the joints may also be present, especially in recurrent attacks.

In the invasion-period the skin does not yet present the perspiratory activity which is so characteristic a symptom of acute rheumatism; but rather a moistness, greasiness or oiliness, with heat and some congestion. The temperature is raised one degree or more. The sore-throat, which consists in pharyngeal catarrh, follicular tonsillitis or even actual acute suppurative inflammation, is remarkably characteristic. The milder forms are soon lost in the more urgent symptoms.

The duration of the stage of invasion of acute

rheumatism varies greatly, the flying pains in the joints 'settling' much more quickly in some cases than in others. In a small proportion of cases the disease is so rapidly developed that the stage of invasion is wanting. The patient on waking in the morning finds one or more joints affected; or he appears to be struck down during the day without the slightest warning; and instances are not unknown in which persons, thus suddenly seized with acute rheumatism, have been removed to hospital for supposed sprain or fracture of the limbs. In rarer instances the feverish symptoms of the invasion-stage may be well marked without any pains whatever.

Declared Disease.—The phenomena connected with the affected joints naturally vary much. The swelling is usually considerable, and is chiefly referable to effusion into the cavity of the articulation, fluctuation being frequently discoverable. It is rare for the periarthritic effusion to be so abundant as to yield pitting on pressure. Neighbouring tendons and tendon-sheaths may be swollen, as well as tender. The amount of intra-articular effusion (as well as the pain) greatly influences the position of the joint, but most joints are maintained in a position a few degrees removed from extension. Careful examination will determine the increase and the disappearance of the swelling, as the joints are attacked and recover respectively.

Pain is the most distressing of all the symptoms in uncomplicated rheumatism. It is always severe, and sometimes almost unbearable; but it varies with the different joints, and with the degree and duration of their involvement. It may be said to increase steadily for several hours; it remains excessive for a time; and it then slowly and steadily declines. Its character is very differently described by different sufferers. When a joint is attacked by rheumatism, the first sensation felt by the patient is one of soreness on movement. As the condition develops, the soreness increases to an ache of a subdued, throbbing character. In the course of a few hours the ache 'works up' into an intense pain, apparently associated with a feeling of cramp, the slightest movement of the articulation being almost unbearable. The severe pain now gradually declines—in some instances from the time the swelling reaches its height. After several hours the only pain that remains is a distressing sensation as if the parts had been severely bruised; and the effusion which accompanied the excessive pain having declined along with it, rest of the joint again becomes all-important, the very slightest movement being sufficient to restore the wearying ache. Finally, the pain completely disappears, and nothing remains beyond a feeling of stiffness and helplessness when the joint is moved.

While the course of the pain of an acute rheumatic attack is usually such as has been described, it is greatly modified by a variety of circumstances, such as the particular joint affected, the age and sex of the patient, the condition of the nervous system, and the presence of certain temperaments. In some instances it is increased at night.

Tenderness is a constant and well-marked symptom of acute rheumatism. Reference has already been made to the effect of movement on the pain in its different stages, especially towards the end; and to the characteristic posture and anxious expression of the patient, who suffers intensely from the slightest shake of the bed, or even a footfall on

the floor. Tenderness finally declines into the feeling of stiffness on movement.

The redness of a rheumatic joint is a simple pink blush of erythema, very rarely purpuric. Its intensity varies much with the superficial or deep situation of the articulation, and it is therefore most marked in connection with the joints of the hands and feet, the knees and the ankles.

Heat of the affected joint is a well-marked objective sign of acute rheumatism. The skin over the articulation feels decidedly warmer to the hand than the surrounding parts; and this observation is confirmed by the thermometer.

The favourite joints involved in acute rheumatism are the larger articulations, especially the knees, ankles, wrists, shoulders and elbows; the hip-joint less frequently than the others. The fingers come next in order of frequency; then the toes; while the remaining articulations are more rarely affected.

Corresponding rather closely with the frequency of attack is the favourite order of invasion; the ankles being most frequently the first to be involved, then the knees, and so on. In other instances it is observed that the disease passes along the joints of the lower limbs, including the hips, to those of the upper limbs; frequently its distribution is symmetrical bilaterally; while in some cases it is unilateral, the homologous joints of the upper and lower limb being simultaneously invaded. The smaller joints suffer, as a rule, towards the termination of the attack.

During the course of acute rheumatism in children and adolescents, more especially in girls, occasionally also in adults, crops of subcutaneous nodules are occasionally developed in connection with the joints, tendon-sheaths and bones. These nodules are said to be fibrous at first, and to contain diplococci (Poynton and Payne). As generally seen they are small fibroid bodies, varying in size from a pea to an almond, and are readily discovered by stretching the integuments over the affected joint, which is best done by gentle flexion. They then stand out as pale elevations on the prominent ridges and prominences of the articulation; firm, scarcely movable, rarely tender, rounded in outline or occasionally acuminate. Several nodules are usually present on a single joint; but as they appear in crops, and have different stages of development, decline and disappearance, their numbers and characters vary from day to day. The favourite joints affected are the elbows, knees, knuckles, wrists and ankles. In connection with the cranium the occipital region frequently presents a great crop of nodules. On the tendon-sheaths of the forearms and hands they are occasionally very distinct, and here they are movable. They have also been found on the vertebræ, clavicle, scapula, sternum, ribs, ilium and long bones. A fact of significance is the usual association of subcutaneous rheumatic nodules, if they are large and numerous, with severe endocarditis and pericarditis.

The muscular pains of the stage of invasion of acute rheumatism disappear in the declared disease, or are lost in the presence of more severe symptoms. They are replaced, however, by pains in the soft parts of the limbs related to the affected joints, especially the muscular insertions and fasciæ; and even the whole limb may ache, with much stiffness and a feeling of utter powerlessness. Painful twitchings are also common, especially during sleep; and when the acute pain has passed off,

marked muscular debility and possibly atrophy remain behind.

Acute rheumatism is attended by well-marked *pyrexia*, but this, like the disease as a whole, is variable in degree, course and duration. The sudden invasion of the several joints, their speedy relief, the alternation of extreme bodily distress with comparative comfort, and especially the variety of pyrexial diseases with which the rheumatism may be complicated, would hardly lead us to expect a typical temperature-curve. Nevertheless, in uncomplicated cases the fever follows a tolerably definite course. *Pyrexia* makes its appearance at invasion; it continues as long as the local symptoms reserve an acute or subacute character; and with them it declines and disappears. The *degree* of the *pyrexia*, in the great majority of cases, is in direct proportion to the severity of the joint-disease. Mild local symptoms—that is, moderate pain, short duration of symptoms in any given joint, and a small number of joints affected—are accompanied by moderate fever, ranging from 99° to 102° F. On the other hand, severe local symptoms—that is, severe pain, the full development of the several signs in the affected parts, and the simultaneous involvement of several joints—are attended by a temperature of 101° to 104° F. In another, but very small, class of cases the temperature, whatever it may have been previously, rises rapidly to an alarming height, so as to be entirely out of proportion to the joint-symptoms, which either continue as before, or even disappear. This condition of *hyperpyrexia* is regarded in the light of a complication, and as such will be presently described.

The *type* of the fever in uncomplicated cases is *emittent*, the thermometer rising 25° , 50° , or 100° F. in the evening. The primary elevation of temperature at the commencement of the disease is somewhat rapid; the decline or defervescence is decidedly more gradual, although it is generally irregular, being almost invariably broken by temporary rises, or interrupted by the supervention of some pyrexial complication. Brief recrudescences of fever, referable to excitement, exertion or neglect of the primary alimentary and eliminative functions, are also common. The occurrence of a true relapse is marked by a return of *pyrexia*, which probably presents the same general characters as before.

Profuse *acid sweats* constitute one of the characteristic phenomena of acute rheumatism. The brow is covered with drops which trickle down the face; and the whole body perspires profusely, and is bathed in an atmosphere of wet steam. Although usually universal, the sweats may sometimes be unequally distributed. It is doubtful whether any relation can be traced between the amount of perspiration and the hour of the day or night, the temperature or the pulse; perhaps it varies directly with the severity of the pain. The sweats continue throughout the whole attack, making their appearance at an early date, and disappearing gradually with the subsidence of the other symptoms. They do not intermit in the striking way of the sweats of the hectic or septic states, except towards the end of a severe protracted attack, when the patient is greatly debilitated; but at certain parts of the day the skin may be found to be perspiring less freely, or even to be perfectly dry. The sweat of acute rheumatism possesses a peculiar sour, acid odour; and this is so powerful, and pervades so thoroughly the neighbourhood of the patient when the blankets

are disturbed, that the diagnosis of the disease can frequently be made from it alone. Like the sweat in health, it is acid in reaction, rarely alkaline from decomposition. No other test can be readily applied to it clinically. The rheumatic patient may complain of the unpleasant, but never of the 'weakening' effect of the perspirations which is observed in hectic fever; on the contrary, he may describe them as bringing great relief to the bodily condition. In less acute cases the skin may present a shiny or greasy appearance, rather than actual perspiration. When the sweats are severe, *sudamina* make their appearance, especially about the trunk; and in some cases the skin is covered with a profuse eruption of *miliaria*.

In connection with the *digestive system*, the tongue is found to be covered with a thick, white, moist fur, which varies closely with the rheumatic condition, and serves as a ready evidence of the same. The thickness of the coating is sometimes very great. Occasionally the tongue is dry; very rarely brown, baked-looking or cracked. The sense of taste is, in a great measure, lost; thirst is urgent and difficult to satisfy; and the reaction of the saliva, or, more correctly, of the fluids of the mouth, is said to become acid. Appetite is lost, until the disease begins to decline, when hunger returns very early and urgently. Sore-throat occurs in some cases during the declared disease, but is much less common than in the stage of invasion. Sickness is rarely present. *Dyspepsia*, attended by flatulence, is common, unless the most digestible food only be given. Irregularity of the bowels is characteristic of acute rheumatism, either constipation or diarrhoea being almost constantly present; and the two conditions frequently alternate. Diarrhoea is perhaps more common in first than in subsequent attacks. The motions are dark and foul. Pains in the belly are by no means rare, and are frequently connected with diarrhoea, but they occur also in constipation; and at times they are accompanied by attacks of distressing flatulence.

The frequency of the *respirations* in simple articular rheumatism is somewhat increased; slight cough is occasionally present; and under these circumstances a few dry rhonchi may be heard over the chest. On the other hand, respiratory affections may be of a serious and even fatal character, and will be considered in their proper place.

Throughout an attack of acute rheumatism the *urine* is scanty, high-coloured and strongly acid; and it deposits a quantity of urates. Temporary albuminuria is not uncommon. Quantitatively examined, the urine is found to contain an actual excess of urea, and a considerable (but probably only a relative) excess of uric acid, sulphates and colouring-matter (*see SPECTROSCOPE IN MEDICINE*); the water is below the normal amount; and the chlorides are diminished, although less so than in pneumonia. Lactic acid has never been found in excess. Any marked departure from these characters of the urine, especially in the appearance of more than a passing trace of albumen, is to be considered as a complication of the rheumatism.

As a rule the *nervous system* is but little disordered in acute rheumatism. Consciousness and clearness of intellect are preserved throughout. Delirium is very uncommon; and when either delirium or stupor supervenes, it will generally be found that, apart from complications or the action

of impure salicylates, the temperature has risen to an excessive height. Very rarely the pyrexia remains moderate in these circumstances, and such cases have been described by the name of 'cerebral rheumatism.' There is generally great distress of mind in acute rheumatism; and, in other than first attacks, the previous experience of its severe and uncertain course and dangers, and the recollection of the pains and other sources of bodily discomfort, greatly affect the patient, and produce an amount of anxiety which is almost characteristic of the disease. Sleep is either impossible, or at best is constantly broken and unrefreshing, when the pain is severe.

The *expression* of the sufferer from this disease calls for brief notice. The debility or prostration, which forms an important element of fever from whatever cause, is present in acute rheumatism, but it is in great measure obscured by the expression referable to pain, and by the effort to preserve an easy position. Towards the end of an attack, when pain is subsiding and movement is comparatively easy, the patient and the practitioner begin to appreciate the degree to which the bodily weight and strength, and the richness of the blood, have been reduced. This loss is always great, and is sometimes extreme, varying, of course, with the severity and duration of the disease.

Cardiac Affections.—These are by far the most frequent and important visceral manifestations of rheumatism, being present in no fewer than 50 per cent. of all cases. The percentage of acute cardiac disease is, however, less than this—almost certainly about one-third, the remaining cases being chronic, or chronic and acute cardiac disease combined. These numbers refer only to structural disease of the heart, namely, simple or ulcerative endocarditis, myocarditis, pericarditis, and the effects of these, singly or in combination. But, besides inflammatory affections, there occur acute dilatation and functional disorders of the heart, characterised chiefly by palpitation, cardiac distress and the presence of various abnormal physical signs. According to some observers, the latter class are of as frequent occurrence as the former. It is probable that the evanescent cardiac murmurs by which they are recognised are produced either by acute dilatation of the ventricle, or by small vegetative growths on the valves which afterwards disappear. When the heart is sound the pulse is regular, 80 to 120, large, sometimes hard, more frequently soft or even dicrotic; but it naturally varies much with the severity and stage of the disease.

The *circumstances* under which cardiac involvement most frequently makes its appearance in acute rheumatism are—first, and specially, early age, rheumatic children rarely escaping disease of the heart, youths seldom, and the liability rapidly diminishing after the thirtieth year; secondly, severity of the rheumatic attack—with which the liability to cardiac affections increases directly—in the adult; thirdly, the female sex—women being more subject to rheumatic disease of the heart than men; and, fourthly, neglect of proper treatment during and after the attack.

The *time of appearance* of cardiac symptoms has been variously stated by different observers. As a matter of fact, they are generally discovered when the patient comes under observation; they certainly begin most frequently in the first week of illness; but they by no means uncommonly make

their appearance in the second week, and may occur at any period.

Inflammation of the heart and pericardium are fully described under their appropriate headings (*see* HEART, Inflammation of; and PERICARDIUM, Diseases of). The influence of the presence of these and other cardiac lesions on the course and prognosis of acute rheumatism is so important as to alter the whole aspect of the case, and to prove the chief cause of anxiety. Affections of the heart are by far the most common cause of death from rheumatism, immediate and remote; and even if they do not prove fatal, they constitute the most distressing of the remote effects of the disease. Rheumatic dilatation and inflammation of the heart in children, like the arthritis in these subjects, are often slight at first, and are therefore liable to be overlooked or disregarded; but they are processes which—partly, no doubt, in consequence of this circumstance—may lead to grave disease.

Respiratory Affections.—Diseases of the respiratory organs have been variously stated to occur in from one in every six to one in every sixteen cases of acute rheumatism; and in the larger proportion of immediately fatal cases they are the direct cause of death—frequently in association with endocarditis and pericarditis. The most common is pleuro-pneumonia; pleurisy alone the next; then pneumonia; severe bronchitis, pulmonary congestion and laryngitis are more rare. They may probably occur at any period of the rheumatic attack; but the gravest forms will necessarily appear towards the termination, for the obvious reason that they so frequently prove fatal. The supervention of acute respiratory diseases is, as a rule, easily recognised by the appearance of their several symptoms and signs.

Affections of Serous Cavities.—Rheumatic pleurisy and pericarditis have been referred to. Rheumatic peritonitis is a very rare but a real disease. Rheumatic 'orchitis,' or inflammation of the tunica vaginalis, is occasionally met with.

Tonsillitis.—This, in different forms and degrees, is a common rheumatic manifestation. It may accompany the arthritis; or precede it by hours, days, or weeks; or be associated with acute endo- or peri-carditis, which proceeds to chronic cardiac disease, while the joints escape.

Chorea.—Chorea bears an intimate relation to acute rheumatism (*see* CHOREA). Occasionally it appears in the course of an attack; and choreic twitchings may thus be the prominent symptoms during the first days of the illness, especially in children.

Cutaneous Affections.—In a small proportion of instances, acute rheumatism, or a condition which practically cannot be distinguished from it, is associated with erythema. Sometimes the arthritic symptoms are the first to appear, sometimes the skin-affection, and the two conditions, or the erythema alone, are further associated with some of the visceral affections already mentioned. Urticaria is less frequently seen in the same connections. A remarkable condition, in which arthritic symptoms are associated with purpura, hemorrhages, vascular thromboses, and possibly ulcerative endocarditis and its complications, is known as *peliosis rheumatica*, or *purpura rheumatica*, but does not appear to be true rheumatism. Sudamina and miliaria have been already noticed. *See* ERYTHEMA; PURPURA; and URTICARIA.

VARIETIES.—The description just given applies to a fully developed attack of acute rheumatism. It is only a minority of cases, however, that are of this nature. Occasionally the symptoms are very mild or the attack is very short, in which event the rheumatism is said to be *subacute*. In another variety or 'type' of the disease, which is common in children, the articular manifestations are insignificant or even 'latent,' but the cardiac, pleuritic and other manifestations are severely marked, and the rheumatic process is peculiarly protracted in the form of relapses and recurrences. These departures from the 'typical' course of acute rheumatism, as it is called, will now be considered.

Subacute Rheumatism.—Under the name of subacute rheumatism are comprised a variety of cases of the disease, which, while of comparatively little severity, exhibit the greatest possible differences in their other clinical characters. Several well-marked groups of these may be distinguished, and demand separate consideration.

The *first* group of subacute cases is one in which the duration of the disease is unusually short—probably from one to three days. The number of joints affected is very small; and the general symptoms appear to be arrested before attaining any considerable severity. In a *second* group of subacute cases, after exceedingly mild invasion-symptoms, a single joint only is attacked, with little pyrexia, while the skin presents a shiny or oily dampness rather than true perspiration. The rheumatism disappears in a few days; or it shortly relapses in the same or in some other joint. This form of subacute rheumatism may be difficult to diagnose from gout. Widely different from the foregoing is another and the most common variety of subacute rheumatism. Such are many of the *recurrent* cases of the disease, and of the instances of first attacks in old subjects. It may be stated broadly that the first attack, or first and second attacks, of rheumatism are more severe than subsequent ones; that the severity diminishes with each recurrence of the disease; and that persons attacked for the first time after middle life suffer less than younger subjects. In all these cases, the phenomena connected with the joints, and the general symptoms, including the pyrexia and the sweats, are mild in degree, although by no means of short duration. In recurrent cases the patients are frequently the subjects of chronic heart-disease, in whom exposure to some of the determining conditions of rheumatism has lighted up fresh endo- and peri-carditis, and therewith moderate fever and subacute rheumatism of the joints. The anxiety of the practitioner will be confined to the condition of the heart; but during the progress of the complaint, joint after joint may become painful, tender, slightly swollen and red.

Acute Rheumatism in Children.—In children and young adolescents acute rheumatism possesses clinical characters so different in many respects from those just described in adults, as to be readily overlooked or mistaken for other diseases, even by the medical attendant. First, the symptoms and signs connected with the joints are relatively mild and may be entirely latent, and the diagnosis is only made on the discovery of acute cardiac disease. The patient is slightly feverish, and may or may not complain of pain and tenderness in the limbs, and of sore throat; moderate swelling of the affected joints passes unheeded;

the pains are either entirely disregarded or referred to 'growing,' to influenza or to 'a cold'; and the sweats are much less profuse or entirely wanting. Secondly, acute rheumatism in these young subjects often commences elsewhere than in the joints—with sore throat, erythema, pleurisy, or pneumonia, or with chorea. In the next place, while the disease in children presents these mild characters, the proportion of cases in which it is accompanied by acute cardiac disease—myo-, endo-, and pericarditis—is comparatively large, a fact which greatly increases the necessity for an early diagnosis. This is accomplished by making it a rule of practice to examine the heart and lungs physically in every case of febrile disease in the child, and that not once only but repeatedly; and at the same time to note with particular attention the colour and expression of the child's face, the posture and the frequency and type of respiration. In addition to these and the discovery of the physical signs of acute inflammation or dilatation of the heart, important evidences of rheumatism in children are the signs of chronic valvular disease—the result of a previous attack, the existence of nodules, the family history, and the effect of salicylates. Lastly, acute rheumatism in children exhibits an exceptional liability to relapse on the slightest departure from the rules of strict treatment and general management in the way of excitement, movement, or premature indulgence in solid food. Relapse takes the same irregular forms as the primary attack: fresh cardiac or pericardial trouble, pleurisy with effusion—particularly on the left side, erythema, tonsillitis, crops of nodules, chorea; and thus cases may be protracted for many months on end, with the further unfortunate disposition to recur in some form or other during the next few years, which in these subjects deserve the name of the 'rheumatic age.'

COMPLICATIONS.—*Hyperpyrexia* is one of the most alarming complications of acute rheumatism, but happily one of the most rare. The condition is fully described in another article (see FEVER; and TEMPERATURE). It may occur at any period of the disease; generally when the symptoms are fully developed; but even during convalescence. The principal indications of the approach of hyperpyrexia, which it is of the last importance to recognise, are flushing of the face; brightness and restlessness of the eyes; an eager, excited expression and behaviour; disappearance of pain and swelling from the joints, and arrest of the perspirations; delirium; and increase of the general symptoms of fever. On the occurrence of any of these symptoms in an otherwise uncomplicated case of acute rheumatism, the temperature should be taken at once, and the observation repeated every half-hour. If the body-heat prove to be over 103° F., and to be still rising, measures must be immediately adopted to prevent the hyperpyrexia which is certainly threatening.

The reputed frequency of *nervous* complications has been greatly reduced since the discovery that the majority of the cases of so-called 'cerebral rheumatism' and 'rheumatic meningitis' are really instances of hyperpyrexia. These cases being excluded, the frequency of cerebral disturbance, in otherwise uncomplicated rheumatism, is not greater than in other pyrexial diseases. Cerebral embolism may occur from endocarditis; meningitis is very rarely observed; insanity has been described in connection with acute rheumatism (see MANIA).

Delirium tremens occasionally supervenes when there is a history of alcoholism. Other causes of delirium in acute rheumatism are pericarditis and the salicylates.

Albuminuria does not occur in more than $\frac{1}{2}$ or 1 per cent. of all cases of acute rheumatism; and the so-called 'rheumatic nephritis' has probably no real existence. The frequency of albuminuria is not greater than can be accounted for by the presence of pyrexia, by renal embolism, by the probable existence of chronic cardiac and renal disease, and by the possible association of scarlatina.

When acute rheumatism attacks a subject of the *gouty* diathesis, its symptoms may be considerably modified. The pain, swelling, and selection of particular joints have all a *gouty* character more or less; and while the disease is more amenable to treatment directed against the *gout*, it has possibly a greater tendency to lapse into a chronic affection of the smaller joints.

Scarlatina may be contracted in the course of acute rheumatism, or during convalescence. The occurrence of rheumatism as a complication or sequela of scarlatina—a much more frequent and important association—is discussed under SCARLET FEVER. The two diseases may mutually predispose to each other, by lowering the general health and increasing the liability to chill; but some authorities hold that the ordinary complications of scarlatina, as well as the arthritis, such as serous inflammations and nephritis, are essentially rheumatic.

COURSE, DURATION, TERMINATIONS AND SEQUELÆ.—The course of acute rheumatism is indefinite. The natural duration under expectant treatment is about three weeks. The average duration of *acute symptoms* under the same treatment has been estimated at nine days; it is rather less under certain other methods of treatment; and it is much prolonged by neglect. The entire duration of an attack is much greater than this, and necessarily less definite, namely, two to six or even ten weeks; and, speaking broadly, it increases with the age of the patient, up to middle age.

The patient being convalescent, a *relapse* of the disease by no means uncommonly occurs, after a few days or weeks. The fresh rheumatism may attain any degree, from a slight swelling, redness and pain of a single joint, to a combination of the various symptoms, as severe as the first, or possibly more so, associated with fresh visceral manifestations. Occasionally two or more relapses may occur.

Convalescence is generally protracted (before the health is perfectly restored); and it is very common to hear persons who have suffered from acute rheumatism give three or four months as the time they were 'ill.' Convalescence is accompanied by desquamation involving the hands and feet, and perhaps the body generally. It is usually marked by obstinate anæmia. In many cases stiffness, pain and weakness continue indefinitely in the joints and neighbouring muscles. Nodules may remain for months.

In children, as described, the disease sometimes assumes an obstinately recurrent type, further dilatation or inflammation of the heart, pleurisy, fresh nodules and possibly chorea making their appearance in various associations, and frequently leading to a fatal result.

The great majority of cases of acute rheumatism

ultimately end in recovery, the proportion of deaths as the immediate result of an attack being only about 4 per cent. On the other hand, a large number of persons suffer from remote effects of the disease, many of which are not only distressing but likely to lead to death. Of the immediately fatal cases, the larger proportion terminate in the first or second weeks, and are associated with, if not actually due to, acute disease of the respiratory organs. The fatal cases which present cardiac disease, especially acute pericarditis, are scarcely less numerous. Altogether it may be said that from a half to three-fourths of all cases of death during acute rheumatism are referable to acute cardiac and pulmonary disease, either separately or combined. It is doubtful whether any patient dies from excessive pain, pyrexia, sweating and consequent exhaustion. Hyperpyrexia is the most common cause of death next to pulmonary and cardiac affections. In a small number of cases, meningitis, acute alcoholism and other complications lead to a fatal termination.

The *remote consequences* of acute rheumatism are, on the whole, more serious than the immediate effects. In a few instances the disease leaves behind it a condition of joints which passes into 'chronic rheumatism' or 'rheumatoid arthritis.' A far more common effect is valvular disease of the heart, which is referable in the majority of instances to acute endocarditis occurring as a complication of rheumatism. It is impossible to estimate the number of cases of disease of the lungs, vessels, brain, kidneys and other organs, which, in their turn, are caused by such heart-disease. It is not probable that the vessels suffer directly from the effects of rheumatism. When, in addition to these effects, we consider the debility, emaciation and anæmia which it induces, the remote effects of pneumonia and pleurisy, of chorea, and of the other less common complications of rheumatism, as well as the liability to a return of the disease and its complications, it is difficult to exaggerate the seriousness of the ultimate results of this malady. See also TABES DORSALIS.

PATHOLOGY.—The pathology of acute rheumatism is still obscure, and in the present article it will be sufficient to enumerate the principal theories that have been advanced respecting its nature. It was suggested that *lactic acid* accumulates in the body, and that the symptoms are directly referable to the action of this poison upon the system (Prout, Todd, Richardson). Other authorities (Canstatt, Seitz) believed that chill of the peripheral parts of the body, especially of the skin and joints, causes disturbance of corresponding parts of the central nervous system, and that this gives rise to pain and vaso-motor (?) or trophic changes of the same peripheral parts, and to fever. A third view was a combination of the two preceding: that chill causes accumulation or retention of lactic acid; that this acts on the central nervous system; and that the disordered nervous centres react upon the joints and other parts (Senator). Fuller and Latham put the relation somewhat differently, maintaining that chill disturbs the nervous system; that this disturbs metabolism generally; and that lactic or uric acid or both are retained, and act as poisons. Bastian (see NEURITIS, MULTIPLE) has suggested that, as the result of chill, some poisonous product is formed within the system, which, according to individual proclivity or the nature of the products engendered,

excites acute articular affection, or multiple neuritis, or acute spinal paralysis. A number of years ago it was suggested by Heter that rheumatism originates with the entrance of micro-organisms into the system; that endocarditis results; and that the joint-symptoms are secondary to this, and embolic, as in pyæmia. Certainly the present trend of opinion is that the disease is due to the presence in the blood of a micro-organism or a variety of micro-organisms (Salisbury, Immermann). These may enter the body by the tonsils or other channel, whereupon their morbid activity may be confined to the lymphatic system, particularly the serous and synovial cavities (Mantle). Once admitted they act specifically on the blood and different viscera, as do the causes of other acute infectious diseases.

Without criticising these theories, we may conclude that, while the true pathology of acute rheumatism is still unsettled, the most promising directions from which we may expect light to be thrown upon it are, first, bacteriology; secondly, the actions of organic poisons, whether introduced from without, or produced within the body as the intermediate products of nutrition; and, thirdly, the intimate relation of the nervous system to the body-heat, to the skin and to nutrition.

The pathological relations of the visceral and serous affections and of the different complications of acute rheumatism are very various. The largest and by far the most important group, comprising cardiac inflammations, pneumonia, pleurisy, peritonitis, erythema nodosum, chorea and meningitis, can only be described as having an intimate *genetic relation* to rheumatism, that is, as being a real part of the disease. This relation is indicated in many ways, such as the frequency of their occurrence during an attack of articular rheumatism; the comparative infrequency of certain of them in any other connection; the manifest analogy that exists between the parts affected in some of them and the joints; the direct increase of their frequency with the intensity of the general rheumatic symptoms, that is, of the cause of the disease; the transient and migratory character which they may present, alternating as they sometimes do with each other and with the arthritis; their occasional occurrence before the joint-symptoms, or even without them, constituting acute rheumatism without arthritis; their appearance in the person of a blood-relation of a rheumatic subject; their amenability to anti-rheumatic treatment; and, lastly, their occurrence in the course of acute rheumatism as a part only of a manifestly general disease.

The complications of acute rheumatism in the more correct sense of the term include certain effects of it, such as albuminuria, hyperpyrexia and mental disorder; scarlatina, dysentery and profuse hæmorrhages, which are perhaps related to it *etiologicaly*; and lastly, bronchitis and delirium tremens, which are to be considered as merely *concomitant* or *intercurrent* conditions.

DIAGNOSIS.—Although acute rheumatism can generally be easily recognised, its diagnosis is sometimes a matter of the greatest difficulty.

In the stage of *invasion*, it is most readily confounded with the acute specific fevers, including influenza and catarrh, in which pyrexia and aching of the limbs are prominent symptoms, and which indeed at times are complicated with rheumatism. If sore-throat be comparatively well-marked, and the development of the joint-affection slow, the

practitioner may be led to diagnose tonsillitis or simple catarrh instead of rheumatism, and to make light of a complaint which is about to develop into a serious disease. In every doubtful case a certain number of facts should be kept clearly in view, namely, the history of the attack; the possible occurrence of previous attacks of rheumatism; the family history; the absence of symptoms characteristic of other diseases, such as eruptions or coryza; the development of pain or tenderness in a definite joint, and of acid sweats; and, most important of all, the discovery of the signs of inflammation of the heart.

In the second or *declared* stage, when one or more joints are involved, an entirely different group of diseases have to be diagnosed from rheumatism, namely, gout, 'rheumatoid arthritis,' gonorrhœal arthritis, pyæmia, glanders, and acute synovitis or arthritis of traumatic or diathetic origin. In doubtful cases the characteristic phenomena of rheumatism must be kept clearly in mind, especially the transient and erratic course of the arthritic symptoms, and the probable presence of cardiac complications.

Acute gout may generally be diagnosed by the sudden invasion at night of a single joint—probably the great toe, in a man of middle or advanced age; by the severity of the pain, which is relieved by the occurrence of a characteristic swelling of the part; by the history of previous attacks of the same description; by the insignificant amount of constitutional disturbance attending the arthritis; and by the strict localisation of tenderness, as compared with swelling, when the acme is passed. The discovery of uric acid in the serum will settle definitely the diagnosis of gout (p. 604).

Pyæmia is usually associated with an injury or pre-existing surgical disease which simplifies the diagnosis. Rigors are the rule, while they are the exception in rheumatism; the fever has a deeply remittent or intermittent character; the sweats are distinctly intermittent; the arthritis is neither transient nor migratory, but may advance to suppuration of the joints; and symptoms of blood-poisoning, splenic enlargement, phlebitis and extensive and multiple visceral disease shortly supervene. Still it is a fact, which cannot be insisted upon too strongly, that cases of pyæmia are frequently mistaken at first for acute rheumatism.

Gonorrhœal arthritis may be recognised by being persistent, whether one or more joints be involved; by the type and degree of the pyrexia, which is not controlled by salicylates; by the absence of cardiac complications as a rule; by the presence of conjunctivitis; and, most certainly of all, by the co-existence of a urethral discharge, containing the gonococcus. See GONORRHOËAL ARTHRITIS.

Chronic rheumatoid arthritis may be distinguished by the characteristic deformities of the joints, but first attacks are readily confounded with acute rheumatism.

For the diagnosis of glanders, see GLANDERS.

Ordinary *synovitis* is rarely multiple. It is persistent and not migratory, and has an appreciable cause, whether traumatic or diathetic. See JOINTS, Diseases of.

The numerous difficulties which beset the diagnosis of subacute rheumatism and of acute rheumatism in children, have already been sufficiently dwelt upon.

PROGNOSIS.—In a disease which runs so uncertain a course, and which may include such a variety

of dangers, the prognosis is necessarily most uncertain. The proportion of fatal cases, and of cardiac affections, and the average duration of an attack, can easily be stated; but in a given case there is at first no positive means of foretelling what course the disease will run in any one of these respects. The prognosis must be specially guarded in persons worn out by mental or physical overwork or anxiety; in young women of full flabby habit, with tendency to anæmia and disturbance of the uterus, stomach and circulation; and in women after delivery—all subjects in whom cardiac inflammation and failure, and pulmonary invasion, are to be apprehended. Ill-declared 'weak' symptoms connected with the joints, indicating that the bodily strength and power of resistance are low, are less favourable than well-pronounced 'honest' pains and a warm sweating skin, which generally point to a favourable termination as regards life. It must, however, be observed that the risk of visceral involvement in some degree increases with the severity of the local symptoms. The probability of cardiac invasion decidedly declines after the first week, but the possibility continues as long as fresh joints are being invaded. Rheumatism of the joints may be expected, on the whole, to run a mild course in children, but it must not be forgotten that the course of it may be protracted by the occurrence of relapses and recurrences; and that the danger of cardiac disease is very great. In old subjects it may be safely assumed that acute rheumatism will end favourably. The supervention of pneumonia or pleuro-pneumonia, especially in association with cardiac disease, or of hyperpyrexia, should cause anxiety, as immediately threatening life. The prognostic significance of nodules is important. Remote danger from acute rheumatism is chiefly to be estimated by the occurrence of heart-disease, and by the form that it takes; and the liability to recurrence with fresh cardiac lesions must never be forgotten.

TREATMENT.—In addition to the ordinary measures proper in every case of an acute febrile disease which will probably prove of some duration, we must especially secure for the rheumatic patient perfect quiet, extreme gentleness of every necessary movement, and the prevention or relief of the discomfort attendant on constant and profuse perspirations. Next to a good strong nurse, and perfect hygienic arrangements of the sick-room, a proper bed is of the utmost importance in the general management of the case. The bed must be firm, stand on a firm floor, be sufficiently narrow, and be placed in such a position as to be readily accessible from either side and allow the attendants to reach any part of the limbs or trunk of the patient without interfering with the position and comfort of the other parts. Further, the bed must be 'made' as a 'rheumatic bed'; that is, a pair of blankets must be placed between the sheets—the one over, the other under the patient, so as to absorb the profuse sweat, and diminish the risk of chill from dampness of the linen. The patient should be furnished with a long flannel bed-gown, made to fasten with tapes down the front and along the arms, so that the chest or any joint may be reached with the least possible disturbance. Arrangements must be made for collecting the urine and stools in bed; and the use of a urinal and a bed-pan, or a properly arranged towel for these purposes, is imperative. Equal care is necessary in the general management

of acute rheumatism in children, however mild the attack may appear to be.

The nursing arrangements being completed, the physician may turn his attention to the consideration of the medicinal and dietetic therapeutics of the case. Two indications have to be fulfilled, namely, first, the control of the morbid process, and secondly, the relief of local symptoms that may be urgent, and the removal of general distress.

Whatever specific remedies may be selected, the medicinal treatment of acute rheumatism should be commenced with a purge consisting of calomel or a mercurial and colocynth pill, followed by a saline.

The use of the *salicylates* and *salicin*, introduced by MacLagan in this country, constitutes the routine drug-treatment of acute rheumatism; and the results obtained from it are certainly more favourable than from any other method. Fifteen to twenty-five grains of sodium salicylate, twenty grains of salicylic acid, or fifteen grains of salicin, are given every one, two, three, or four hours, until the temperature falls to the normal, to establish rapidly the full therapeutical influence of the drug; after which the dose is very gradually reduced, so as to be simply sufficient to maintain the apyrexia and control the arthritis for several (seven to ten) days. Some authorities reduce the dose as soon as symptoms begin to yield. The salicylates are best given in watery solution, variously flavoured; salicylic acid in milk, or combined with solution of ammonium acetate; and salicin in wafers or in solution. Different practitioners prefer the different forms of the active substance; the sodium salicylate is most extensively used. The salicylates reduce the temperature to the normal in the course of twenty-four to seventy-two hours, relieve the pain and other arthritic symptoms, markedly improve the condition of the patient generally, and diminish the risk of cardiac affections. The effect is most marked in first attacks, and in the early stages of an attack.

Unfortunately there are several drawbacks to the use of the salicylates. The first of these is the fact that the rheumatism frequently returns as soon as their exhibition is stopped. On the second or third day after the disease has been checked, the symptoms may be again as severe as at first, and the risk of cardiac involvement again present. Thus it happens that, taking an average of a large number of recorded instances, the total duration of rheumatic symptoms is not less than nineteen days. Still, in a considerable proportion of cases no such relapse occurs, and the patients are completely relieved within forty-eight to sixty hours.

Secondly, while the salicyl-compounds have a considerable influence in preventing visceral affections, by rapidly controlling the specific morbid process, they yet frequently fail to do so; and further, they appear to have little or no effect in subduing such visceral affections as may have already commenced. But if they do not arrest the endocarditis, pericarditis or pleurisy, they will repeatedly dispel the arthritic symptoms that may recur again and again during the course of these internal manifestations of the rheumatism. The best rule to follow, therefore, is to restrain the arthritis and fever by means of sufficient but not excessive doses of salicylates, and to attend to the indications presented by any visceral inflammation that may arise. The salicylates will be resumed or increased, as the case may be, in the event of recrudescence, inas-

much as pyrexial rheumatism, however slight, always depresses the heart.

Thirdly, the salicyl-compounds—particularly if abused—occasionally produce toxic symptoms, such as deafness, tinnitus, delirium, great frequency and weakness of the pulse, flushing of the face, lividity, sickness and collapse; and the termination may be fatal. The depressant action of salicylates on the heart and circulation especially is dreaded by practitioners, who are sometimes too ready to give them up for alkalis and quinine on the appearance of cardiac manifestations. In obstinately recurring cases, also, the protracted use of salicylates is believed to aggravate instead of controlling the rheumatism, by depressing the vitality of the patient. Of the two toxic influences, however, the salicyl-compounds are, in the writer's opinion, far less dangerous than rheumatism; and failure of the heart may be prevented by combining them with digitalis, ammonia, strychnine, ether or alcohol. Further, it has been determined that some of the worst of the toxic effects of salicylates were caused by impurities in the acid prepared artificially from phenol, which are now removed in the process of manufacture. Sodium salicylate can be given by the rectum to children, or to adults when the stomach is intolerant of the drug.

Lastly, it must be confessed that in a very small number of instances the salicylates entirely fail to control the arthritis and fever. The practitioner ought not to conclude that this is the case until he has tried the effect of larger doses. Twenty-five or thirty grains of the sodium-salt will often answer perfectly after twenty grains have been given without obvious effect. Salicin or salol (phenol salicylate) may succeed under the same circumstances.

If the salicylates fail or disagree, recourse must be had to alkaline treatment or to some other method. Certain practitioners combine alkalis with the salicylates from the first; others prescribe alkalis in diminished doses, or equal parts of sodium salicylate and bicarbonate. Possibly anæmia may be more marked, and convalescence more slow, after treatment with salicylates.

Before the introduction of the salicyl-compounds *alkalis* were in general use in the treatment of acute rheumatism. The alkaline method consists in the internal administration of sufficiently large doses of certain alkaline salts, such as the carbonates, citrates, tartrates and acetates, to render the urine quickly alkaline; in maintaining this reaction as long as the rheumatic symptoms continue; and in gradually allowing a neutral or an acid reaction to return by diminishing the dose as the symptoms decline. To obtain the full effect of potassium upon the system, half a drachm of the bicarbonate in an ounce of water should be prescribed at once, either alone or with citric acid in the effervescing form; and the dose is to be repeated every four hours. An equal amount of potassium acetate may be added to each dose, if a still more rapid and powerful action of the alkalis be desired. The urine will probably become alkaline within twenty-four hours; and when once this effect has been obtained, it may very easily be kept up by continuing the alkalis at longer intervals, which may be further increased as the symptoms decline. The effect of the drugs upon the patient must be carefully watched, and the amount and frequency of the dose varied accordingly, or its administration stopped, if necessary. Finally, when the rheumatism is relieved,

quinine may be added to the alkaline mixture; and as convalescence advances, the potassium may be entirely withdrawn. Constipation occurring in the course of treatment may be relieved by combining tartarated soda with the bicarbonate, tartaric acid being used to cause effervescence; or, if more obstinate, with a calomel and colocynth pill. It is claimed for this method that, as the alkalis begin to exhibit their action on the system, the whole aspect of the case becomes more favourable, the general distress being alleviated, the temperature falling, and the local symptoms relieved; that these favourable effects continue to become more and more marked, until the rheumatic condition has disappeared; that the average duration of the attack is greatly shortened, not exceeding 6·75 days in the acute stage and 13·5 days before the disappearance of pain; and that the proportion of visceral affections is reduced as low as 2 per cent. only.

The alkaline influence upon the system may be further increased, in a very agreeable way, by supplying the ordinary effervescing potash or soda water as a drink, either alone, or combined with milk or with fresh lemon-juice. The patient may be encouraged to drink this in quantity, unless there be special indications to the contrary, such as cardiac distress. Should there be diarrhoea, lime-water may be substituted for the potash or soda water. Should alkalis persistently cause purgation, their administration must be discontinued.

A modification of the preceding plan has been highly recommended by Sir Alfred Garrod, and consists in the administration of quinine from the very first in combination with large doses of alkalis; as much as five grains of the alkaloid (thus in the form of a carbonate) being given every four hours.

The most obvious general remedies for the relief of distress are anodynes and antipyretics. So much benefit follows the use of *opium* in some cases, by relieving pain and diminishing nervous irritability, that it has acquired a reputation even as a specific. Although formerly given in large and frequent doses, such as a grain every three to eight hours, either alone or combined with mercury, *opium* is now seldom employed in acute rheumatism, except in the form of a moderate dose of Dover's powder, or of a morphine draught at night, to relieve pain and induce sleep. The effect of the opium must be carefully watched, in the presence of the complications which may possibly arise and contra-indicate its use.

Many other antipyretic remedies besides the salicylates have been recommended, such as phenazone, acetanilide and phenacetin; quinine, tartar emetic, veratrum, digitalis, aconite, mercury and various diaphoretics. The use of quinine has been already referred to. At the present time reliance is chiefly placed upon two powerful remedies of this class, namely, the cold bath and the wet pack.

The cold bath is the most powerful and speedy method of reducing the temperature in acute rheumatism, but is seldom resorted to except in cases of hyperpyrexia. When this condition threatens, the cold bath (p. 136) or the wet pack (p. 699) is to be unhesitatingly employed, in the manner described elsewhere (*see* FEVER; FEBRIFUGES; and TEMPERATURE). If the symptoms be less urgent, cold sponging of the trunk may be sufficient to reduce the temperature.

Hæmatinic remedies may be considered to be indicated by the great anæmia which accompanies and yet more markedly follows an attack of acute rheumatism. Russell Reynoldson recommended iron perchloride in large doses; and favourable results have attended the administration of it in the acute phase. During convalescence iron is invaluable.

Empirical remedies.—Lemon-juice appears to have proved successful in some cases of acute rheumatism in doses of eight ounces or less in twenty-four hours. Other drugs include propylamine and trimethylamine, in four- to eight-minim doses every two hours; potassium nitrate to the amount of an ounce in the twenty-four hours; cynara or artichoke; and the cyanides of potassium and zinc. Colchicum may be given with advantage for rheumatism in a gouty subject, to relieve pain. Guaiacum is useful in sub-acute lingering cases. Potassium bromide has also been found very useful in American practice, probably by relieving pain and restlessness.

Reference must here be made to the observations of Gull and Sutton upon the course of acute rheumatism when treated by simple rest and the exhibition of a *placebo*. The comfort of the patient is secured by ordinary means; and small doses of opium are given to complete this effect when indicated. The results were favourable, but less so than those of several other methods of treatment, nine days being the average duration of acute symptoms. The frequency of cardiac invasion was also low.

For an account of the treatment of the visceral affections and the complications of acute rheumatism, the reader is referred to the respective articles on each of these in other parts of this work (see HEART, Inflammation of; LUNGS, Inflammation of; PERICARDIUM, Diseases of; HYDROTHERAPEUTICS (p. 700); &c.). The plan of treatment which is being pursued for the rheumatism may have to be temporarily suspended or considerably modified on the appearance of any of these grave conditions, but the salicylates ought not to be stopped without good reason, as already described.

The state of the bowels requires the most careful attention. Constipation must be relieved by any of the ordinary means. Diarrhœa may be checked with lime-water or bismuth, or with a judicious dose of castor-oil, according to its cause. The surface of the body should be regularly sponged with a very weak tepid solution of an alkaline carbonate.

The most ready and satisfactory measure for the *relief of local distress* is the application of absorbent cotton-wool to the rheumatic joints. This is to be wrapped in some quantity around the parts, and secured with a moderately firm roller, or a piece of warm flannel with the ends stitched together. The affected articulation is thus at once kept at rest and protected from cold and pressure; while uniform support is obtained. The relief afforded by this simple arrangement is often remarkable. The joints should be carefully sponged with warm water and soap, or warm water slightly alkalisied with sodium carbonate, before this or any other application; and the cotton-wool must be occasionally changed, especially if perspiration be profuse.

When the pain is still more severe, and relief is not to be obtained by simple rest and protection, anodynes may be applied to the rheumatic joints.

Opium in any of its ordinary preparations, belladonna and its allies, and other familiar anodynes, may severally answer best in particular instances. These substances may be applied on the surface of lint, secured and supported by a bandage; or the affected part may be lightly rubbed or smeared with the anodyne preparation in the form of liniment, and then wrapped in cotton-wool or flannel, as already described. Heat is generally grateful to acutely rheumatic joints, but in many cases it is felt to be useless in the acute stage unless it be quite extreme. Thus simple warm fomentations give relief; but the patient may urgently demand their constant renewal, so that they may be almost scalding. There are obvious objections to this treatment. Extreme cold has been recommended by some authorities, notably Professors Esmarch and Hueter, in the form of ice. It is seldom used in this country. A method of treatment once much in favour with some physicians, consisting in the application of blisters to the rheumatic joints, has been abandoned.

Certain lotions, of other than direct anodyne properties, have been recommended as local applications, to produce a specific effect upon the rheumatic joints, and thus indirectly afford relief. The chief of these are alkaline solutions, especially solutions of the carbonates of potassium and sodium, saturating flannel wrapped loosely around the joints. They may be combined with preparations of opium. Their value is somewhat doubtful.

The proper *diet* in acute rheumatism is the same as that in most other kinds of fever. The patient must be fed at short and regular intervals, night and day, with the most digestible forms of liquid nourishment; and may be encouraged to drink milk, or milk and soda-water, occasionally. It must not be forgotten, however, that in all probability the system is already overloaded with the products of imperfect assimilation and transformation; that the digestive system is weak and irritable; and that the heart may be seriously affected by flatulence, and by the addition of much fluid or solid material to the blood. As the acute symptoms decline and appetite returns, fish, milk-puddings, and shortly afterwards chicken, sweetbread, and other 'light' articles of diet, may be cautiously allowed, and will be greatly relished. But, as a rule, the appetite returns before it can be safely indulged without risk of a relapse. Meat must be strictly forbidden until every rheumatic symptom has disappeared; and it is a correct therapeutic rule not to give solid food and salicylates together. Thirst is best relieved in the acute stage, as already stated, with aerated alkaline waters, either alone or in combination with lemon-juice or milk, the quantity given being regulated by the practitioner and accurately recorded.

Alcoholic stimulants, in moderate doses, are indicated when the symptoms are severe and protracted. Besides this routine use of alcohol, a special virtue was claimed for its free administration, as in other fevers, by Todd and his disciples, in preserving the strength and relieving the pain. Brandy must be ordered on general principles in cases attended with extreme depression, or with serious visceral involvement, especially in the event of cardiac failure.

The general management of a case of rheumatism after the decline of the acute symptoms is scarcely less important than at the commencement of the

attack. The patient should be encouraged to keep his bed for several days after the disappearance of the joint-symptoms. This advice becomes imperative when the heart is involved. Rest and comfort of body and mind must be secured at this period, for the purpose of quieting the action of the heart, and allowing cardiac weakness and any endocarditic process that may affect the valves, and that probably outlasts the articular process, to subside quietly. The appetite must still be controlled, and daily evacuation of the bowels carefully attended to. All attempts at completing the cure of acute rheumatism within a certain small number of days must therefore be avoided. Even with these precautions, the first day of sitting up generally proves an anxious time to the practitioner in cardiac cases. Locomotion must be forbidden for several days, and permitted very gradually. When the patient is able to move about and go into the open air, the danger of a relapse during the first weeks must be carefully kept in mind. Sudden and extreme changes of temperature are especially to be avoided; and for this purpose the patient must be warmly clad, and studiously avoid draughts and exposure to cold in other forms. Hydrotherapeutic treatment is often successful in protracted cases, particularly if the articular symptoms are more prominent than the febrile. Careful rubbing or exercises, or in other cases a course of baths and massage at Droitwich, Bath or Buxton, may give excellent results independently of medicine.

Tonics are indicated during convalescence; for example, quinine and iron, separately or combined either with alkalis or acids, and strychnine. Tonics must not be commenced too early.

In the obstinately recurrent type of the disease occasionally met with in *children and adolescents* our therapeutical resources and patience are severely taxed. In the majority of instances the heart is seriously involved, and demands chief consideration; but attempts to treat the cardiac disease are usually vain unless the associated rheumatism, *however slight*, be directly combated. The most rigid and continuous attention to diet, elimination and rest, on the principles already laid down, is an indispensable element of the treatment—or, more correctly, the management—of rheumatism in this phase. As often as pain and pyrexia reappear, salicylates must be had recourse to if they can be borne, and iron and other tonics very cautiously resumed when the temperature has been reduced.

In persons who have suffered from acute rheumatism means ought to be adopted to prevent the return of the disease at a future time. The unfavourable influences to be chiefly avoided are cold and damp localities, exposure to wet, chill after exertion, free eating and drinking, and neglect of the liver and bowels. Woollen garments ought to be worn, summer as well as winter, in this country, of different thickness according to season and weather. These precautions are particularly important in the instance of rheumatic children. When the heart has been damaged in young subjects, so much attention is paid to the cardiac condition, with its attendant anæmia and impairment of nutrition, that the practitioner as well as the parents forget that one of the greatest dangers to which the child is exposed is return of rheumatism and fresh endocarditis.

J. MITCHELL BRUCE.

RHEUMATISM, Chronic.—SYNON.: Fr. *Rhumatisme Articulaire Chronique*; Ger. *Chronischer Rheumatismus*.

DEFINITION.—A disease of the joints, of chronic course; referable to certain obscure influences, possibly of a diathetic, climatic, or infective nature; and characterised by various degrees of inflammatory and degenerative changes in the articular and associated structures.

ÆTIOLOGY.—The causes of chronic rheumatism, as far as they are known, are the same as those of the acute disease. The most powerful predisposing circumstances are inheritance, previous attacks of acute rheumatism, poverty, physical and mental exhaustion, and laborious occupations entailing exposure to chills. For the last reason men are more liable to the disease than women, and certain joints are its favourite seats. Chronic rheumatism is most common in middle life or advanced age, although by no means rare in young adults, and occasionally met with in children. Exacerbations of the symptoms are usually referable to exposure, and are accordingly most frequent and protracted in cold, wet weather. Occasionally they appear to follow influenza.

ANATOMICAL CHARACTERS.—A variety of anatomical changes may be met with in chronic rheumatism, while in the least severe form of the disease no definite lesions of the articular structures can be discovered. In one form recurrent hyperæmia and effusion are found in connection with the synovial structures, and with the articular and peri-articular tissues generally. In the most severe cases the joints are enlarged and deformed, in consequence of anatomical changes which appear to be identical with those of rheumatoid arthritis (*see RHEUMATOID ARTHRITIS*). The heart is often the seat of chronic valvular disease and enlargement.

SYMPTOMS.—The clinical characters of chronic rheumatism vary extremely in different instances. The leading symptoms of the disease are chiefly two, namely, pain and stiffness in connection with the joints and associated structures, recurring indefinitely for any length of time, aggravated by cold, wet weather, and decidedly increased at night. More carefully investigated, the pains are found to have their seat in the joints, in the tissues of the limbs between the joints, or in both of these situations. Any or all of the articulations may be affected, but the site differs considerably in the different classes of the disease to be presently described. The pain is of a severe aching, wearying character, attended by a sense of heaviness and uselessness of the limb; it is relieved by rubbing, and by exposure to a cold atmosphere; and is increased by slight warmth. Free use of the joint, although at first attended by pain, often affords temporary relief; while, on the other hand, undue exercise of the limbs during the day is liable to be followed by severe aching in the night. The affected joints also feel markedly dry and stiff, and creak on movement; but exercise or rubbing may remove these sensations. These symptoms may last indefinitely for years, either recurring at intervals, especially in the winter and spring seasons, or being persistent almost day and night without intermission.

In the mildest degree the pain and stiffness just described are the only articular symptoms present. No anatomical change is apparent in either the joints or associated parts. The subjects of this

form of the disease may be otherwise well, vigorous and long-lived, in spite of the severe pains by which their rest is broken in cold, wet weather. They may or may not have, or have had, acute rheumatism.

In a more severe form of chronic rheumatism the pain is associated with obvious anatomical changes; and the disease takes the form either of a sequel of acute rheumatism or of recurrent subacute rheumatism, making its appearance at intervals for years. The articular phenomena consist of pain, redness, tenderness and swelling, the hands being a favourite seat of the affection. These attacks last indefinitely, shift from joint to joint, and leave behind them a distinct amount of swelling, which may not have completely disappeared before another invasion.

Thus chronic rheumatism of the most marked degree ultimately leads to enlargement and deformity of the affected articulations, the disease gradually invading the joints both large and small, until the whole articular system may be involved. After some years the subacute attacks follow so closely upon each other, and their local effects are so severe, that the patient is never free from distressing pain; the joints become ankylosed, dislocated, and otherwise disorganised; and the associated muscles undergo atrophy. At the same time the general nutrition is gradually impaired; and the sufferer is anæmic, wasted and debilitated. Chronic rheumatism of the most severe degree thus merges into the class of disease known as 'rheumatoid' arthritis, if it be not actually identical with it. See RHEUMATOID ARTHRITIS.

In other subjects the joints enlarge slowly without pain.

COURSE AND TERMINATIONS.—The disease, as its name implies, is essentially chronic, generally lasting throughout the life of the individual whom it attacks, and leading to various conditions of debility and deformity, according to the degree of its intensity. In many instances the patient is rendered unfit for work; and such cases form a considerable proportion of the inmates of Poor-Law infirmaries and other charitable institutions. Death as a direct result of the disease is rare.

COMPLICATIONS.—Myalgia and neuralgia, referable to rheumatism, are frequently associated with the arthritic trouble. Cardiac disease is met with in a considerable number of cases belonging to the more severe degrees of chronic rheumatism, being usually referable to endocarditis, which complicated the original acute attack. Dyspepsia is not infrequently seen in the subjects of the less severe forms. Iritis may be a very troublesome complication.

PATHOLOGY.—This disease is truly rheumatic in its nature, being intimately associated with acute rheumatism. In many of the best marked instances the patient has previously suffered from the acute disease, either immediately before or more remotely; in other instances one or more acute attacks occur in the course of the chronic disease. In another group of cases, a single member of a family will suffer from chronic rheumatism, ending in deformity, while his children, or his brothers and sisters, are attacked by the acute disease. The predisposing and exciting circumstances are also the same in acute and chronic rheumatism. Indeed, the two forms of affection run into each other in every particular, and are inseparably associated.

DIAGNOSIS.—The disease most often confounded with chronic rheumatism is chronic gout, particu-

larly that form of the disease characterised by pains in the limbs only, or that in which the joints—particularly those of the fingers—become enlarged and deformed with the development of articular nodes (*nodus digitorum*) and without tophi. Chronic arthritis may be regarded as gouty when the family history points in that direction; when the patient's history includes the occurrence of megrim, eczema, asthma, fits of depression and insomnia, glycosuria, lithæmia, and a disposition to obesity; and when any cardiac lesion that may be present belongs to the degenerative or senile instead of the inflammatory or juvenile type. It must be observed, however, that the two diseases are occasionally associated; and that then only is the name 'rheumatic gout' (so constantly misapplied) employed properly.

If chronic rheumatism be regarded as a distinct disease from 'chronic rheumatoid arthritis,' it is only in its most severe form that it can be confounded with the latter. A definite history of acute rheumatism; the presence of cardiac disease; and the non-involvement of such articulations as the jaw, the sterno-clavicular joint, and the spine, are considered to be features which render probable the diagnosis of true chronic rheumatism from rheumatoid arthritis.

The pain, swelling, heaviness, weariness and weakness associated with varix of the lower extremities, sometimes resemble closely the symptoms of the milder forms of chronic rheumatism. Physical examination at once removes all doubt.

PROGNOSIS.—The prognosis of chronic rheumatism is favourable as regards life, but very unfavourable as regards recovery. Patients rarely lose the tendency to recurrence of pain throughout the whole of their life. Within a short time of the commencement of the disease it will be easy to discover which of the principal forms it is likely to assume; and the prognosis may be made accordingly.

TREATMENT.—The leading indications for treatment in chronic rheumatism are, first, to control the pathological process; and second, to relieve the distress which characterises it.

The best possible measure for treating the *pathological process and the constitutional condition* with which chronic rheumatism is associated is removal of the patient to a warm and settled climate in some sub-tropical or tropical country. For persons of more moderate means we have recourse to warmth of clothing and housing and relief from muscular exertion, as far as they can be secured; for the very poor these advantages are secured by admission permanently into charitable institutions. The subjects of chronic rheumatism require a nutritious, heat-producing, and at the same time attractive and digestible diet, with a small allowance of alcohol at meal-times in the form either of spirits and water or of a pure red wine. The action of the liver and bowels must be carefully attended to. Iron, cod-liver oil and arsenic are the drugs best suited to improve the health; iodides and sulphur sometimes prove useful. Occasional large doses of salicylate of sodium will control more urgent symptoms. If acute symptoms, particularly pyrexia, supervene, liquid nourishment should be given. Courses of the mineral waters of Bath, Buxton and Strathpeffer in this country; and of many foreign baths, such as Aix-les-Bains, Royat, Aix-la-Chapelle, Wiesbaden, Baden-Baden and Hammam R'Hira, prove inval-

able in many cases to those who can afford to try them. As a rule, massage forms part of the treatment at these places; and passive movement of the joints, slowly but steadily increased in degree day by day, can be practised readily at home with much hope of benefit. Exercise should be taken daily in the open air, unless the weather be unfavourable; and active movement of the other joints besides those of the lower extremities should be maintained in spite of temporary pain. See RHEUMATOID ARTHRITIS.

Directions for *palliative treatment* are always desired by the patient. This chiefly consists in counter-irritation by iodine or cantharides; the application of anodynes, such as preparations of opium, belladonna and chloroform; or friction with various stimulating liniments, containing camphor, soap, turpentine or acetic acid. Regular warm ointmentations night and morning with very warm or even hot water, followed by rubbing and the application of a stimulating liniment under warm rollers, is one of the most efficacious methods of local treatment, the pains being prevented or relieved, and the stiffness removed often to a remarkable degree. The ordinary Turkish bath may also afford temporary relief, if properly employed (p. 137). Altogether, whatever view may be taken of the pathology of the disease, thorough local treatment of the joints and limbs will generally be attended with decided relief.

J. MITCHELL BRUCE.

RHEUMATISM, Muscular.—SYNON.: Fr. *Rhumatisme Musculaire*; Ger. *Muskelrheumatismus*.

DEFINITION.—A disorder of fibro-muscular structures, characterised by local pain and spasm, and a certain degree of fever; and generally associated with the rheumatic diathesis.

ÆTIOLOGY.—Muscular rheumatism is most frequently observed in the subjects of the rheumatic diathesis. It occurs in both sexes, and at all ages; children and adolescents being specially liable to rheumatic torticollis, and older subjects to lumbago and chronic muscular rheumatism of the limbs. The exciting circumstances are chiefly two: first, exposure to cold—above all, exposure of a muscular part to a 'draught' after exertion; and second, sprain or strain of the fibro-muscular structures. A peculiarly obstinate type of the disease has been observed as a sequela of influenza. Muscular pain, tenderness, and spasms are also common in the invasion of acute rheumatism, in chronic articular rheumatism, in chronic gout, and in gonorrhoeal arthritis.

ANATOMICAL CHARACTERS.—Nothing is known respecting the anatomical characters of muscular rheumatism, if, indeed, there be any discoverable change in the muscular or fibrous structures.

SYMPTOMS.—The disorder usually commences with slight febrile disturbance, possibly accompanied by sore-throat. Either simultaneously—possibly, indeed, quite suddenly—or in children after one or two days, pain is experienced in the region of some definite muscle or muscular mass, such as the sterno-mastoid or the muscles of the joints; and this speedily becomes so severe as to constitute the leading symptom of the attack. The pain is present only when the affected muscle is thrown into action, so that it may be perfectly relieved by relaxation or rest of the parts involved.

The slightest movement, however, from the position of relief is instantly attended by excruciating pain, of a peculiar spasmodic character, which persists until relaxation is again secured. The constant effort to avoid pain gives rise to a feeling and appearance of stiffness, causing the patient to assume characteristic attitudes of the head, trunk or limbs. Tenderness on grasping the muscle is occasionally well-marked. In some cases several of the joints may also be affected with pain and stiffness.

The constitutional symptoms of muscular rheumatism are generally those of mild fever. The tongue is furred, the appetite is impaired, the bowels are confined, the pulse is somewhat frequent, large and soft, and there is a feeling of malaise. Cases certainly also occur where the fever both in its type and in its severity resembles that of ordinary acute rheumatism. In other instances these symptoms are extremely slight or altogether wanting, the patient suffering from nothing more than local pain. Occasionally there is catarrhal ophthalmia. Subacute articular rheumatism and sciatica may be present as complications.

Muscular rheumatism usually persists for several days, and gradually declines, but in the more severe cases or in the milder cases it may last for weeks. One form of the disorder is essentially chronic, the patient suffering for years from pain in various fibro-muscular structures, especially those of the shoulder, arm, thigh and leg, during cold wet weather.

VARIETIES.—The following local varieties of muscular rheumatism are recognised by special names:—

1. **Muscular Torticollis.**—SYNON.: Acute Wry-neck; Stiff-neck; *Caput Obstipum*.—Here the sterno-mastoid muscle is chiefly involved, but any or all of the cervical muscles may be painful. This form is most frequently observed in young subjects, and is often markedly recurrent. It is easily recognised by the fixed position of the head; and has to be diagnosed from spasmodic torticollis, sterno-mastoid tumour, sprain, tonsillitis and spinal disease.

2. **Pleurodynia.**—The fibro-muscular structures of the chest-wall are the seat of rheumatism in this variety. Cough is a common exciting condition of the complaint, which is seen chiefly in adults. Pain is complained of in the chest-wall, usually on one side; in some instances it may be excruciating, and of a distressing, spasmodic character. On examination, we find that a particular intercostal space, or the origin of the pectoral or serratus muscle, is the seat of localised tenderness; and that every respiratory act causes lancinating pain in the same situation. The respiratory movements of the affected side are restrained; but the ordinary physical signs of pleural, pulmonary and cardiac diseases are absent, as are also the *points douloureux* that characterise intercostal neuralgia. If the movements of the corresponding ribs be restrained by plaster or bandage, the pain is effectually controlled. The direct constitutional disturbance is generally not great, unless sleep be prevented by pain.

3. **Lumbago.**—The muscular and fibrous structures of the loins are here the seat of pain—most commonly the erector spinæ, less commonly the latissimus dorsi, or other smaller muscles in the same situation, on one or both sides. As the

muscles of the back support the body in the erect position, and participate in the various movements of rising and bending the trunk in all directions, the patient may be compelled to remain at absolute rest in bed. More frequently he is able to move about, although with pain or in a stooping attitude. The amount of febrile disturbance is generally moderate.

Lumbago is easily recognised by the characteristic muscular pain referred to the loins, greatly increased by bending, straightening the back, rising from the sitting posture, or turning in bed; and by tenderness of the muscles on pinching, without the acute defined tenderness on pressure of abscess or neuralgia. At the same time it cannot be insisted upon too strongly, that careful examination of the back, of the abdomen generally, and of the urine will be required to prevent the practitioner from falling into the not uncommon error of treating cases of serious disease as simple lumbago. Renal calculus, lumbar abscess connected with spinal caries, perinephritis, perityphlitis, abdominal aneurysm, disease of the rectum, uterus or bladder, influenza, spinal meningitis, and small-pox, are the principal morbid conditions which must be borne in mind and excluded in every instance, before the diagnosis is settled. Pain in the loins is also a very common accompaniment of affections of the buttock and lower limbs, such as sciatica, rheumatic affections of the hip-joint, and perhaps lameness from any cause. It is also very frequently met with in gonorrhoeal arthritis.

4. **Omodynia.**—**SYNON.**: Dorsodynia; Scapulodynia. — These names are given to rheumatism involving the structures of the upper part of the back and shoulders. It occurs chiefly in persons much exposed to the weather; and has to be diagnosed chiefly from rheumatism of the shoulder-joint, and certain less common forms of neuralgia connected with the upper dorsal nerves and arms, thoracic aneurysm, and diseases of the cord and spine.

5. **Abdominal Rheumatism.** — Muscular rheumatism of the abdominal walls is occasionally observed, either alone or in association with lumbago.

6. **Cephalodynia.** — Muscular rheumatism may affect the scalp, giving rise to a dull, aching kind of headache, on the brow or occiput, aggravated by movement, and occasionally complicated with tenderness of the eyeballs and ophthalmia.

DIAGNOSIS. — Speaking generally, muscular rheumatism has chiefly to be diagnosed from neuralgia, and, as a rule, this can easily be done by the paroxysmal character of the latter, the etiological relations, and especially the physical signs. A very similar disorder that occurs very commonly in gouty subjects must be carefully distinguished (*see* RHEUMATISM, CHRONIC: Diagnosis). The practical diagnosis of the chief local varieties has already been sufficiently indicated.

PROGNOSIS. — The prognosis of muscular rheumatism is highly favourable. Under careful treatment recovery may be anticipated in a few days or weeks. But the disorder is one which is peculiarly liable to recur on exposure to its exciting circumstances.

TREATMENT. — The treatment of muscular rheumatism consists in remedying the constitutional condition; and in relieving the local pain. At the very commencement of the illness, a hot-air or

Turkish bath may answer both these indications, and give immediate relief. The first indication will, however, generally be best fulfilled by free purgation, followed by alkaline salines, such as potassium bicarbonate, citrate or acetate, and solution of ammonium acetate. In more feeble subjects quinine may be given combined with alkalis; or in protracted cases potassium iodide. The diet should be of the simplest character.

The best local treatment consists in absolute rest and warmth of the affected parts, which may be variously secured in different instances by confinement to bed, strapping and plasters. Mustard is one of the most available and successful of remedies. Other counter-irritants or anodynes which give great relief are warm opiate fomentations, or liniments composed of extract of belladonna and glycerine, opium, aconite, chloroform or camphor, or of various combinations of these. Liniments are more efficacious when sprinkled on the surface of a hot fomentation, firmly applied, than when rubbed into the part. If the suffering be great, a hypodermic injection of morphine and atropine should be given. Belladonna plaster gives at once relief and support in mild cases. The continuous galvanic current occasionally dispels the pain and stiffness almost immediately. A prolonged hot or mustard bath, carefully given, relieves some cases of lumbago. In obstinate cases cupping or blistering may be tried. The affected muscles must be kept warm and carefully protected from cold, especially in torticollis. When rheumatism involves the muscles of the limbs, warm anodyne liniments are the best local measures.

Great care should be exercised to prevent the recurrence of muscular rheumatism, by wearing warm woollen clothing; by avoiding exposure to damp and draughts; by attending to the digestion and the bowels; and by abstaining from severe, sudden, and awkward muscular efforts. In chronic or recurrent cases of the disorder, the patient should, if possible, visit some of the English or foreign baths mentioned in the article on RHEUMATOID ARTHRITIS. J. MITCHELL BRUCE.

RHEUMATOID ARTHRITIS.—**SYNON.**: Osteoarthritis; Rheumatic Arthritis; Rheumatic Gout; *Malum Coxæ Senile*; *Fr. Rhumatisme Nouveau*; *Usure des Cartilages Articulaires*; *Ger. Arthritis Deformans*.

DEFINITION. — A disease, the essential nature of which is unknown; mainly characterised by chronic degenerative and inflammatory changes of the articular and associated structures; and leading to deformity.

ÆTIOLOGY. — Persons of all ages may suffer from this disease, including children, but it generally begins between twenty and forty. It is believed to be more frequent in women. Depressing influences of all kinds unquestionably act as predisposing factors. They include acute diseases—such as influenza—menstrual disturbances, chronic uterine disease, frequent pregnancy, puerperal disease, superlactation, the menopause, prolonged physical exertion, privation, unhealthy surroundings and mental distress. The disease is hereditary, appearing in the same form or as acute or chronic rheumatism. In a certain proportion of cases, rheumatoid arthritis follows acute rheumatism immediately, or it appears after an interval of several years, during which time chronic rheumatism of a milder degree

may have been complained of. Gout is very often present in the family history, and not uncommonly tuberculosis also.

The influence of cold and damp as exciting circumstances is very marked. In some instances injury of a joint is the starting-point of the morbid process. Occasionally it follows gonorrhœal arthritis. A variety of micro-organisms have been described as the efficient causes of the disease.

ANATOMICAL CHARACTERS.—Two well-marked forms of rheumatoid arthritis are met with, according as a single joint only, or several—perhaps all—of the joints are affected. The anatomical characters are identical in the two forms.

Examined at an *early* stage of the morbid process, an affected joint is found to be enlarged; the synovial membrane, capsule and ligaments being distended and stretched by a considerable amount of effusion. Bacilli with specific characters have been found in the fluid by some observers. The synovial membrane is hyperæmic, swollen and thickened; its fimbriæ are enlarged and vascular; intra-articular fibro-cartilages, ligaments and tendons are vascular and softened; and the articular cartilages are partially removed, leaving a roughened, vascular, porous-looking surface behind.

In the more *advanced* stage of the process the effusion is considerably less, or may be completely re-absorbed; and the capsule and ligaments are much thickened or even partially calcified. The intra-articular structures, including fibro-cartilages, ligaments, tendons and articular cartilages, may have disappeared in great measure, leaving little or no trace behind. Peculiar bodies, consisting of pendulous masses of fibro-cartilage, are attached to the interior of the synovial membrane; more rarely they are free. The articular cartilages, where their opposed surfaces are in mutual contact, are replaced by an ivory-like layer of bone; while at other parts the surfaces present a pink colouration, with small spots of more intense hyperæmia. The articular surfaces are variously altered in shape and size. Thus articular cavities are widened, and occasionally deepened, by enlargement of the circumference, in the form of 'lips,' or by the production of separate bony masses in the same situation. The heads of bones are enlarged; present similar 'lips' or sharp edges at their widened margins; become flattened at right angles to the axis of pressure; and thus preserve their relations with the corresponding cavities, but can be readily dislocated from them. The shafts of the bones may be considerably altered in shape, increased in size, and changed in density. The associated tendons are frequently dislocated from their course beside the articulations, and atrophied or actually absorbed. The corresponding muscles are similarly atrophied. Bursæ in the neighbourhood of joints may be distended with fluid, and contain fibro-cartilaginous bodies; perioritis may also occur. The anatomical changes in this disease frequently present a remarkably symmetrical distribution. Peripheral neuritis occasionally accompanies the arthritic lesions.

SYMPTOMS.—The symptoms of rheumatoid arthritis in its condition of full development are exceedingly characteristic. The patient complains of pain and stiffness in connection with one or more joints; and on examination these are found to be swollen, more or less deformed, and tender. The history of these changes in the joints proves to be that first one and then others of the articulations were

the seat of acute arthritis, and became painful, tender, hyperæmic and swollen; that the resulting enlargement had not completely disappeared before the acute symptoms recurred; and that, by a repetition of similar acute or sub-acute attacks, the joints have reached their present condition. Thus the disease, while chronic in its course, consists essentially at first of recurrent acute or sub-acute attacks, which increase in frequency while their effects persist, and so finally become fused, as it were, into a continuous whole.

The *local* symptoms and signs vary with the particular joint affected; but in every instance they are chiefly these—pain, tenderness, creaking on movement, impairment of mobility, enlargement and deformity in connection with the joint, and atrophy of the associated muscles. The pain is generally distressing, and may render the patient's life miserable by its continuousness and severity, especially as it increases at night and prevents sleep. It is aggravated by movement, and there is tenderness on forcible disturbance of the articular surfaces rather than on pressure. Creaking or crepitation, audible and palpable, is a highly characteristic feature, which can be elicited and appreciated either by the patient or by the practitioner, and in the case of large joints may be so loud as to be audible at a distance.

The mobility of the affected joints becomes more and more impaired as the disease progresses—at first on account of pain, afterwards in consequence of anatomical changes. Thus the various joints may become fixed by a 'false' (very rarely a 'true') ankylosis, so that the hands cannot be closed; the wrists are immovable; the arms can hardly be moved from the side; the jaws are fixed; the head cannot be rotated; the patient may be unable to sit; and the knees, ankles and toes may be similarly impaired in function.

The variety of deformity is almost endless; and the particular character it assumes depends as much on the joint involved as on the nature of the process itself. Thus the knee, elbow, wrist and knuckles may present considerable intra-articular effusion, especially in the earlier stages; while the shoulder, hip and inter-phalangeal joints exhibit more limited swelling and 'drier' signs. The terminal digital joints become cuboidal or 'nodous'; the middle digital joints assume a spheroidal shape, or are partially dislocated backwards or forwards; and the knuckles are the seat of a peculiar oblique dislocation of the fingers towards the ulnar side. The lower ends of the radius and ulna project backwards, and give a full appearance to the dorsum of the wrist, which may be further increased by extra-articular puffiness, carpal and bursal enlargements, and atrophy of the muscles of the hand and forearm. Altogether, the hands and wrists are the joints most frequently affected. The elbow-joint is swollen; and bursal collections—fluid and solid—develop over the olecranon. The shoulder presents signs of wasting, rather than of enlargement, due to atrophy of the deltoid and other muscles; the head of the humerus at the same time lies unnaturally forwards and upwards; and a corresponding depression is apparent behind. At the hip-joint the disease gives rise to flattening of the buttock, shortening of the limb, and eversion of the foot; enlargement can sometimes be felt in connection with the head of the bone and acetabulum; occasionally the patient may be not only

lame but unable to sit, and accordingly must either stand or lie constantly. The knee, a very common seat of the disease, is enlarged by the presence of considerable effusion in the earlier stage; and when this afterwards becomes absorbed, local bony growths are easily felt, giving increased breadth to the patella, and forming sharp crests at the lateral margins of the articular surface of the condyles. The disease as it affects the ankle and foot does not require special description. At the temporomaxillary articulation rheumatoid arthritis gives rise to obvious enlargement in front of the ears, and possibly to distortion or asymmetry of the chin. Prominent nodular swelling is the principal sign of the disease at the sterno-clavicular articulation. In the spine it chiefly produces rigidity, as well as pain locally and down the arms, and leads to a variety of permanent deformities, with which contractures and distressing spasms of the extremities are sometimes associated.

The *general* condition of the subject of rheumatoid arthritis, when it is advanced, is one of debility and anæmia. The face is pale and expressive of suffering; the complexion is muddy. The skin is peculiarly inactive, and rarely perspires. The patient looks pinched, and complains of a feeling of cold; the extremities are often miserably cold and livid; but the palms of the hands are damp or even soppy. Pyrexia, rising to 101° with considerable remissions or intermissions, may be present in the active phases. Bodily activity is greatly impaired, owing to interference with the movements of the limbs; in many instances the patient is completely crippled and bedridden. Even the voice and the hearing may be impaired, from involvement of the laryngeal and auditory articulations. Pains in the muscles and along the nerve-trunks and in the extremities may accompany or possibly precede those in the joints; and spasms or attacks of 'muscular rheumatism' occur occasionally. Myotatic irritability is frequently increased. The various bodily functions are feeble, and frequently deranged; and although the mind may be active, the condition is rendered wretched in the worst cases by pain, deformity and helplessness. In a considerable proportion of cases (5.75 per cent., Brachet) the patient is the subject of chronic valvular disease of the heart. Kent Spender drew attention to the frequent occurrence in rheumatoid arthritis of other symptoms variously associated with the disease: gastric crises; increased tension and frequency of the pulse, which may rise to 120 or more; excessive pigmentation of the skin, in the form of symmetrical patches, streaks or spots; and yellow bruise-like blotches on different parts of the body.

COURSE AND TERMINATIONS.—The course of rheumatoid arthritis has been already described. Unless it be treated early, the disease progresses essentially towards deformity. Death from rheumatoid arthritis is rare; its other distressing effects have been sufficiently indicated.

PATHOLOGY.—Great diversity of opinion prevails as to the essential nature of this disease. While most authorities acknowledge acute rheumatism as a cause of rheumatoid arthritis, many of them regard it as simply one of the many possible sources of chronic articular irritation. The view most generally held in this country appears to be that it is a disease distinct from rheumatism and gout. Hutchinson maintains that, in a certain

number of instances, there is an element of gout, as well as of rheumatism, in the disease. Ord makes light of the diathetic element, and attaches most importance to a nervous factor in the pathology of this disease, which he regards as a dystrophy of joints, muscles and other associated tissues, traceable to direct or reflex affection of nervous structures, or to general nervous depression. Kent Spender also holds that the affection of the joints is merely one sign of a profound nerve-disorder. Archibald Garrod argues strongly in favour of the dystrophic theory of the disease. The writer's experience is in favour of the strictly rheumatic nature of rheumatoid arthritis, as was maintained by Todd and by Charcot and French authorities generally. In many cases he has found that the morbid process started in an attack of ordinary acute rheumatism, as was originally represented by Adams of Dublin. In numerous instances the family history is distinctly rheumatic. The frequent association of heart-disease is very important evidence in the same direction. Finally, no sharp line can be drawn between acute and sub-acute cases of rheumatism, between sub-acute and chronic cases of rheumatism, or between chronic rheumatism and so-called 'rheumatoid arthritis.' Dyce Duckworth considers it a manifestation of a basic arthritic stock or diathesis—a rheumatic branch of this stock, and therefore a true rheumatism.

DIAGNOSIS.—The diagnosis of rheumatoid arthritis necessarily depends upon the view entertained of its pathology. If considered a distinct disease, it is, as a rule, easily separated from gout by the entire absence of tophi about the joints and in the ears, by the history of the disease, by the absence of manifestations of irregular gout (*see* RHEUMATISM, CHRONIC: Diagnosis), and, in doubtful cases, by the absence of uric acid in the blood. From chronic rheumatism, as ordinarily defined, it is diagnosed by the amount of deformity present. Charcot's disease of joints is known by its nervous associations, and hypertrophic pulmonary osteoarthropathy (p. 19) by precedent affections of the chest. Chronic synovitis of traumatic or constitutional origin may be occasionally mistaken for rheumatoid arthritis; but the presence of the latter disease in several joints, probably symmetrically, should remove all doubt. Rheumatoid arthritis of the hip and shoulder has been confounded with 'dislocation' and 'intracapsular fracture.'

PROGNOSIS.—The prognosis of this disease is favourable as regards life, but unfavourable as regards cure, comfort, or ability to follow active bodily employment. The prognosis is much better in the rich, who can seek relief by change of climate in the earlier stages, than it is among the poor, in whom the disease must in a measure be allowed to pursue its progressive course.

TREATMENT.—The treatment of rheumatoid arthritis must be applied in two directions: first, to arrest, if possible, the morbid process; and secondly, to relieve distress and disability. In a large number of cases the second indication only can be fulfilled, for the disease is frequently too advanced, or the circumstances of the patient are too poor, to afford a prospect of cure.

In the *early stages* of the disease much can be done by energetic treatment, which must be partly constitutional and partly local. If circumstances permit, the patient should be advised to visit, according to the season of the year, the baths either

of Great Britain, of Germany, or of France in summer, or the Algerian springs, the French Riviera, or Italy in winter. Buxton, Bath and Strathpeffer are the best home baths. Aix-les-Bains, Aix-la-Chapelle, Baden-Baden and Wiesbaden may be recommended from May till September. The other places named, especially Hammam-R' Hira, in Algiers, are winter resorts. At all properly appointed bathing establishments massage now forms a part of the treatment. The climate of Egypt proves beneficial in some instances, while a voyage to the tropics or subtropics will suit other patients; and in every case a bright, dry, cheerful locality should be selected for residence if possible. See MINERAL WATERS.

The most valuable internal remedies for rheumatoid arthritis are cod-liver oil, iron, quinine and arsenic. Cod-liver oil should be taken regularly if the digestion permit. Either iron or arsenic, or the two combined, should be taken in full doses for periods of weeks or months, and their effects carefully noted. Sir Alfred Garrod especially recommends the syrup of ferrous iodide. For acute distress, particularly pain, salicylates may sometimes be given with success. In obstinate cases a trial should be given to potassium iodide, and to guaiacum.

The diet should be carefully ordered. While all excess is avoided, as well as indulgence in malt liquors and rich indigestible dishes, a generous supply of mixed animal and vegetable food and wholesome stimulants will be found to be most suitable. The patient should take advantage of every possible opportunity of enjoying daily outdoor exercise in fresh air and sunshine. The clothing must be warm, flannel or other woollen material being worn both summer and winter. Great care must be exercised to avoid cold and damp, in the routine of daily life and in the choice of a residence.

The local treatment is to be considered of hardly less importance than the constitutional. On the first appearance of the disease, counter-irritation should be freely employed around the joints by means of tincture or of strong solution of iodine, which may be used until the skin becomes of a mahogany colour. The joints should then be carefully protected by cotton-wool or flannel, and kept at rest by means of bandages or other means of support, according to the part that is involved. At the end of the sub-acute attacks of the disease, efforts must be made to restore the healthy nutrition of the affected joints by removal of the support, and by local stimulation and graduated exercise. Joints that can be easily reached should be thoroughly fomented night and morning, by wrapping a piece of dry cambric or flannel around them, and sponging water over this, as hot as can be borne. After ten minutes of such treatment the joints should be unwrapped, carefully dried, and then thoroughly rubbed, either with a stimulating liniment, such as the turpentine or acetic turpentine liniment, with a mild mercurial ointment, or with some bland oil, such as cod-liver oil or goose-grease. A light warm covering is then to be applied. The effect of local treatment of this kind, if pursued steadily, is often remarkable, mobility being restored in cases where the joints have been useless for months.

In very advanced cases, especially in old subjects, it is manifestly unreasonable to expect much improvement. Anodyne treatment is then chiefly

called for, and a good deal can be done in this direction by suitable mechanical arrangements and well-chosen local applications, the preparations of opium being, of course, the most successful. Phenazone may relieve pains and spasms of the crippled limbs. The general health will demand support by a well-regulated diet, residence in a warm, dry, moderately bracing climate, and the internal treatment suggested above.

RHINITIS (ῥίς, the nose).—Nasal catarrh. See NOSE, Diseases of.

RHINOLITHS.—See NOSE, Diseases of; and CONCRETIONS.

RHINOPHYMA.—See ACNE ROSACEA.

RHINORRHOEA.—See NOSE, Diseases of.

RHINOSCLEROMA.—See NOSE, Diseases of.

RHINOSCOPY.—See NOSE, Examination of.

RHONCHAL FREMITUS.—A physical sign, appreciated on palpation of the chest, elicited by the act of breathing when certain secretions or other materials are present in the larger air-tubes or in a cavity. See PHYSICAL EXAMINATION.

RHONCHUS (ῥέγκω, I snore).—Rhonchi are sounds heard on auscultation when the air-channels are partially obstructed. The term is restricted by some authors to the so-called *dry* and more or less musical sounds produced in the bronchial tubes, for instance, *sonorous* and *sibilant* rhonchus; the bubbling and crepitating sounds in chest-disease being spoken of as *râles*. By other authorities, again, all such sounds, whether sibilant or crackling, are described either as *rhonchi* or as *râles*, the terms being interchangeable. See PHYSICAL EXAMINATION.

RICKETS (O. E. *wrikken*, to twist).—SYNON. . *Rachitis*; Fr. *Rhachitisme*; Ger. *Rhachitis*; *Englische Krankheit*.

DEFINITION.—A general disease, affecting the nutrition of the whole body; arresting natural growth and development; perverting and delaying ossification; retarding dentition; causing the bones to become soft, and to yield to pressure, and the muscles and ligaments to waste; and in many cases producing alteration of the brain, liver, spleen, and lymphatic glands.

ÆTIOLOGY.—Rickets is the consequence of slow impairment of nutrition, and the causes which produce it are principally—bad feeding, foul air, damp cold rooms, want of sunlight, want of exercise, and want of cleanliness. Of these, perhaps the first two have the greatest influence in causing the disease; for if the quantity of nutritive material introduced into the system be restricted by an improper selection of food, and if the oxidation of waste matters be hindered by an insufficient supply of fresh air, interference with nutrition is necessarily carried to a high degree. A pure bracing air will by itself do much in counteracting the effects of an improper dietary, for it has been noticed

that injudicious feeding is less hurtful in country places where the air is dry than in large towns. This, however, may be partly explained by the greater vigour of the digestive organs in the former case, enabling the child to derive nourishment from food which, under other conditions, would be in-nutritious. Some children are affected more readily and more severely by these causes than others, for the more the strength of the child is reduced before the actual exciting causes of the disease come into play, the more quickly does the patient fall a victim to their effects. Therefore, all influences which impair the general strength, such as weakness in the parents, or, in the case of the child himself, an attack of acute disease, or even unusually troublesome dentition, must be looked upon as predisposing causes of the disorder. There is no proof that rickets is hereditary. A tubercular family predisposition renders the occurrence of rickets unlikely. Some years ago a distinguished foreign physician attempted, by arguments drawn chiefly from morbid anatomy, to prove rickets to be invariably a consequence of inherited syphilis; but the reasons for rejecting this hypothesis are overwhelming.

ANATOMICAL CHARACTERS.—The bones are affected in three ways: growth is retarded; the spread of ossification into parts still cartilaginous is interfered with; and bone already ossified is softened. The growth of bone is not completely arrested; it rather becomes irregular. There is considerable development of the cartilaginous epiphyses, and also of the fibrous periosteum; but these parts ossify incompletely and slowly; and as the normal increase in size of the medullary cavity continues in the usual way, the bone comes gradually to consist less and less of osseous substance, and more and more of, as yet, unossified matter proliferated at the circumference. It is in this way that the bones become soft, and not from any abnormal absorption of earthy salts from bone already ossified. The process of calcification itself, besides being retarded, is abnormal: it has indeed been described as rather a process of petrification than of true ossification. On account of the softness of the long bones, serious deformities ensue, as will be afterwards described. The flat bones become greatly thickened from proliferation of the periosteum. This is especially noticeable at the edges of the cranial bones; and when ossification is completed, the sutures of the skull can be felt to be prominent. In parts, however, and especially in the occipital bone, the osseous substance becomes thinned in places from absorption under the pressure of the growing brain. This condition, which is called 'craniotabes' (p. 350), can be detected by palpation. Ossification is very slow in the cranial bones, and the fontanelle often remains open long after the end of the second year. See SKULL, Diseases of.

The liver, spleen, lymphatic glands, and kidneys are sometimes enlarged. The increase in size is due, not to the presence of any foreign growth or deposit in these organs, but to irregular hypertrophy of their fibrous and epithelial elements, conjoined with a deficiency in earthy salts—an alteration analogous to the changes in the bones. The brain is enlarged from an increase of the neuroglia, not of the nerve-elements. The voluntary muscles are small, pale, flabby, and soft. Under the microscope their striæ are seen to be indistinct. The urine

contains less urea and uric acid than natural, but more phosphates, especially phosphate of lime.

The exact nature of rickets has yet to be discovered. All evidence is against the hypothesis that the nutritive fault lies in the excessive formation of lactic acid, as suggested by Heitzmann, or that the complaint is produced by deficiency of lime in the food, as was at one time supposed. Mercoli and others attribute the disease to a process of auto-infection by streptococci and staphylococci. According to this theory the organisms are absorbed from the alimentary canal into the blood and are deposited in the various organs, especially in those parts—such as the nervous system and the bones—where development is most active. In the bones they set up a chronic osteomyelitis of a special type.

SYMPTOMS.—In most cases the symptoms proper to rickets are preceded by others which indicate a certain amount of interference with the digestive functions. There is occasional vomiting; the bowels are often relaxed; and the motions are habitually loose, pasty-looking, and offensive.

The beginning of the disease is marked by profuse sweating of the head, face, and neck; this is especially seen if the child fall asleep either at night or in the day. Almost at the same time he begins to throw off the bed-clothes at night. He will do this even in winter, and may be seen lying almost naked in the coldest weather. Characteristic changes soon occur in the bones. The ends of the long bones enlarge; the flat bones become thickened; and all the bones lose their firmness and grow softer. These changes affect the osseous system as a whole, and lead to serious deformities. If the child had been able to walk, he becomes unsteady on his legs, or even loses the power of walking altogether. He sits or lies about; is drowsy in the daytime; and at night moves his head restlessly from side to side, so as in many cases to wear the hair off the occiput. The flesh is soft and flabby; the motions remain loose and offensive; and the child appears to be occasionally troubled with abdominal discomfort, for he may be found asleep in his cot, resting upon his hands and knees, with his head buried in the pillow. When the bone-affection is pronounced the child shows strong dislike to being touched or played with. This wish for quiet is usually ascribed to tenderness, but is more probably occasioned by the knowledge that movement hurries the breathing and raises a demand for air which the chest-wall with its softened ribs is unable to satisfy. If evident tenderness be present, the symptom usually indicates that the case is becoming complicated with scurvy.

A prominent symptom in rickets is the deformity produced by alterations in the shape of the skeleton. The softened ribs yield readily to pressure, and it is to pressure, and not to the force of muscular action, as was at one time supposed, that the distortions are chiefly due. The long bones become bent and twisted. The direction of the bending depends upon the direction in which the force of pressure is applied, and in the lower limbs will therefore manifestly vary according as the child can or cannot walk. Sometimes, however, if the disease begins before the child is able to support himself upon his feet, the lower limbs may escape deformity altogether. In such cases they are usually small and thin, with weak, flabby muscles; but the bones

themselves are straight. Force of gravity is another cause of deformity of bone. Thus, in the humerus there is often a curve where the deltoid is inserted; this is produced in great measure by the weight of the hand and forearm when the limb is raised by the deltoid muscle.

The skull is elongated from before backwards; the anterior fontanelle is wide; the sutures are thickened; the forehead is high, square, and sometimes prominent; and the head generally looks large. By palpation of the occiput the condition named 'craniotabes' can sometimes be detected early in the disease. The face appears unduly small when compared with the head, for the growth of the facial bones is arrested. On account of this pause in the development of the jaw-bones dentition is delayed; but the teeth are not only slow to appear, they are also deficient in dental enamel, so that they are no sooner cut than they begin to decay.

The spine is curved on account of muscular and ligamentous weakness; and if this weakness be great, the natural posterior curve of the spine is so much exaggerated as almost to simulate angular curvature. It disappears, however, at once when the child is lifted up by the shoulders. Sometimes the spine is curved laterally.

The deformity of the chest has the following characters: The softened ribs sink in so as to present a groove passing downwards and outwards on each side of the sternum. The bottom of the groove is formed more by the ribs than the cartilages, so that the enlarged ends of the ribs, looking like a row of beads under the skin, can be seen lying along the inner side of the groove. The sternum is forced forwards by this bending of the ribs, and the antero-posterior diameter of the chest is increased. The deformity is due to the pressure of the external air. In healthy breathing this pressure is overcome by the resistance of the thoracic walls, aided by the force of the inspired air. In the rickety child the resistance offered by the softened ribs is greatly reduced, and they therefore sink in at the parts where they are least supported. On account of the softened state of his ribs, the breathing of a rickety child is quick and laborious.

The pelvis is pressed upon from above by the spine and the abdominal contents, from below by the heads of the thigh-bones; and the direction of these forces varies according to the position of the child. The general shape thus produced is triangular, and the pelvic cavity is often greatly narrowed.

A rickety child is short for his age; for his limbs, besides being bent, are stunted, growth in them being more or less arrested. His joints are large, and loose from relaxation of the ligaments. If the disease be severe, the child gets anæmic and wastes, and the muscles become very flabby and small. His belly is big, even where there is no splenic enlargement, from shallowness of pelvis and flatulent accumulation. Such children give little trouble. They are quiet, and seldom cry if left alone. They are late in walking, late in talking, cut their teeth late, and in nursery phraseology are 'backward children.'

COMPLICATIONS.—One of the chief characteristics of rickets is the *intense sensitiveness to cold* with which it is always accompanied; and it is to hills in different forms that a large proportion of deaths occurring in this disease must be attributed. A catarrh may affect the chest or the belly, and in

either case the complication is a very dangerous one.

A pulmonary catarrh in a young child should never be made light of, on account of its tendency to cause collapse of the lung; and if the child be the subject of rickets, the danger is really imminent on account of the softness of the ribs.

If the chill affect the abdomen, as it is very apt to do, an intestinal catarrh is set up; and unless the diarrhoea be quickly arrested, the strength of the child becomes seriously reduced.

Besides its influence in increasing the susceptibility of the body to cold, rickets also heightens the *nervous excitability* of the child. This effect is not a common result of mere weakness, for in an ordinary case of malnutrition with wasting, the natural sensitiveness of the nervous system to external impressions is impaired. It must be therefore looked upon as a peculiarity of the rickety state. Its effects are seen in the attacks of laryngismus stridulus, tetany, rotatory spasm, and convulsions to which these children are so liable. Few cases of laryngismus occur in children who are not the subjects of rickets. Such patients usually have carpo-pedal contractions, and are liable to be convulsed upon the very slightest provocation. On account of the backwardness of the teeth in this disease, all nervous derangements are commonly attributed to dentition; but in rickets dentition, although delayed, is not necessarily troublesome; in fact, the teeth, when they appear, are often cut with singular ease.

Another important complication is *infantile scurvy*; indeed, in the child scurvy is rarely seen apart from rickets. It is not that the complaint is due directly to the general impairment of nutrition upon which the rickety state depends, but that owing to the impoverishment of the blood the patient has become peculiarly susceptible to a scurvy diet, and if fed largely upon tinned foods rapidly develops the disease.

Infantile scurvy is rarely seen before the sixth month, and is most common between the tenth month and the twelfth. For some days the infant is noticed to be getting pale and spiritless; then suddenly he shows signs of pain when he is washed and dressed. The legs are evidently tender. If able to stand, the child refuses to put his feet to the ground, and cries if required to do so. He shows a great dislike to movement, and as the tenderness increases begins to keep his lower limbs flexed upon his body. He lies quietly in his cot, sometimes moans as if in pain, and screams at the slightest touch. At this time the lower parts of the thighs, the knees, or the legs may be noticed to be swollen, but the colour of the skin is unaltered. The swelling is bilateral and is due to extravasation of blood beneath the periosteum. As a rule it is limited to the parts named, but in exceptional cases may affect the arms, especially about the elbow and wrist or the shoulder. Sometimes there is slight œdema. While these local symptoms continue there may be moderate fever (101°–102° at night), but more often the temperature is normal. The complexion is pallid, with a faint sallow tint; and the child is very feeble and sweats profusely. There are usually petechiæ and bruise-like patches on the skin, and hæmorrhages may occur from the nose, the bowels and the kidney; indeed, hæmaturia is a far from uncommon symptom. If a tooth has been cut, the gums may be spongy and sore, and they

are sometimes excessively swollen. If, however, the complication occur before dentition has begun, the gums are rarely affected. In the worst cases there may be separation of the epiphyses of the affected bones. The child then ceases to flex the limb, and lies with it stretched out as if paralysed.

Under appropriate treatment improvement is rapid. In an ordinary case the more urgent symptoms subside in a few days, and even in bad cases recovery is rarely long delayed. A separated epiphysis under favourable conditions becomes again united with the bone, and the patient quickly regains colour and strength. See SCURVY.

Sometimes rickets is accompanied by *chronic hydrocephalus*; the excess of fluid is, however, small. This complication is often suspected where it does not really exist.

DIAGNOSIS.—When the symptoms of rickets are well marked, the bony distortions themselves are sufficiently characteristic to make the nature of the disease unmistakable. It is, however, of great importance to recognise the early symptoms of the disorder, so that by prompt treatment we may prevent the osseous and other changes taking place. It must be remembered that loss of flesh is a late symptom, and that a rickety child is not necessarily a thin one. If an infant pass the ninth month without any appearance of a tooth; if his wrists enlarge; and if on enquiry we find that he is subject to head-sweats at night, and likes to lie naked in his cot, the diagnosis of rickets may be made without hesitation. Weakness of the legs in a young child is often a source of anxiety to parents, and a medical practitioner is consulted because the child is twelve months old and cannot stand. In these cases the early signs of rickets will almost certainly be discovered. Looseness in the joints is common in those cases of rickets, where the symptoms of the disease manifest themselves at the end of the second year. The relaxation of the ligaments is not as a rule combined with much bone-deformity, although it may be so. Weakness of the legs from rickets is distinguished from essential paralysis by the fact that, although there may be no power of standing, the child is yet able to move his limbs; and that the muscles, although weak, are not powerless.

When scurvy occurs it is important not to misapprehend the nature or gravity of the complication. Early treatment is essential to quick recovery, and delay adds greatly to the child's suffering, if it do not put his life in danger. Marked tenderness in a rickety baby should suggest scurvy at once; and if the child scream loudly, while holding both legs flexed and motionless, our suspicions are amply confirmed. Even if swelling be trifling or absent, gentle manipulation will detect thickening round the shaft of the bone at the seat of tenderness. This is especially likely to be found round the femur for some distance above the knee. In addition, the gums may be spongy, although this symptom is often absent; and there may be petechiæ or bruise-like patches, or even unhealthy sores, on the skin.

PROGNOSIS.—The duration of rickets is dependent upon the duration of the causes which produce it. So long as the unhealthy influences under which the disease originated are in operation, the morbid processes continue; but when a better hygiene is adopted, and failing nutrition is restored, recovery begins.

When recovery takes place, the symptoms gradually become less intense and finally disappear. The

enlargement of the joints greatly diminishes, and even the bony distortions become notably reduced, while the bones themselves become thick and strong. Growth, however, is not rapid, and, if the disease have been severe, the child seldom reaches the average height.

When the disease terminates fatally, it is usually through one of the complications which have been mentioned. Sometimes the child sinks and dies, apparently worn out by the intensity of the general disease; but even in these cases the immediate cause of death is usually asphyxia, through the softened state of the ribs. One cause of the great mortality from bronchitis in children is the frequency with which that complaint attacks rickety subjects, even a mild catarrh being dangerous when the ribs are much softened.

In estimating the prospects of recovery in any particular case, we must pay attention to the amount of chest-distortion; and to the presence or absence of disease of the glandular system. If the ribs be much softened, there is always cause for anxiety; and if in a case of pulmonary catarrh there be great recession of the lower ribs in inspiration, the condition is a serious one. The presence of any complication, except perhaps chronic hydrocephalus, necessarily increases the gravity of the case.

TREATMENT.—As rickets is the direct result of malnutrition produced by the unwholesome conditions in which the child has been living, our first care must be to alter these conditions. We must see that the living-rooms are thoroughly ventilated; that the child is taken out regularly into the open air; that he is warmly dressed; and that in his daily bath the washing-process is conducted rapidly so as to avoid a chill. We must next select for the patient a diet which is at once sufficiently digestible and nutritious. The term 'digestible' as applied to diet is a relative term. Food digestible to one infant is indigestible to another, and food readily digested by a child in his natural state of health becomes indigestible to him when his stomach is temporarily weakened by teething or any febrile attack. It is not, however, sufficient that the diet should be digestible; it must also be nutritious. Children kept too long at the breast frequently become rickety, even although fed at the same time upon other and suitable food; for the watery breast-milk, which forms the principal part of their diet, is sufficient by its bulk to satisfy their desire for food, without supplying the required nourishment to the tissues. Rickety children at the breast should at once be weaned, and, if under twelve months old, should be fed principally upon milk guarded with saccharated solution of lime, in the proportion of fifteen drops to the bottleful. They may take, besides, broths, bread and butter, and occasionally the yolk of an egg lightly boiled or beaten up with milk. Instead of bread and butter, the milk may be thickened for some meals with Chapman's wheat-flour baked in an oven; but farinaceous food should be given with very great caution to these children, on account of their tendency to acid indigestion, which renders a starchy diet particularly likely to disagree. Under twelve months of age the child can seldom bear more than one teaspoonful of a farinaceous powder twice in the day. After the first year, strong beef-gravy, and flower of broccoli stewed, may be added to the diet. At sixteen or eighteen months old, a little mutton may be given, carefully pounded in a warm mortar. A mealy

potato, well boiled and mashed, may be allowed, but the effect of all farinaceous food is to be carefully watched. The presence of flatulent pains is a sure sign that the proper quantity has been exceeded. Often in rickets digestive power is very feeble, so that even with the most carefully regulated diet improvement is halting and progress slow. When this is the case, great advantage may be derived from the use of papain, giving one grain in a teaspoonful of water with a grain of bicarbonate of sodium immediately before each meal.

The diet and general sanitary arrangements having been regulated, the secondary question of drug-giving has to be considered. Before adopting tonic treatment, it is important to improve the condition of the bowels. A dose of castor-oil or of rhubarb and bicarbonate of sodium should be given to clear away undigested food, and afterwards a few grains of bicarbonate of sodium with a drop of tincture of opium in a little aromatic water will soon remove the offensiveness of the motions. Citrate of iron may then be ordered, and the child should begin at once to take cod-liver oil. The dose of the oil should be small at first (m xv-xx), and while it is being taken, the motions should be watched for any reappearance of oil in the stools; if this occur, the dose is too large, and must be diminished. As convalescence advances, other medicines may be given; and iron wine, quinine, and reduced iron are all useful. So long as the previous directions have been attended to, the exact tonic used is of comparatively little moment; but cod-liver oil should never be omitted from the treatment. Lime has been strongly recommended by some authors, but according to the writer's experience is of little value unless combined with iron. It may once more be repeated that in rickets the success of treatment is in direct proportion to the conscientiousness with which the rules relative to diet and general management have been carried out; and the mother should be made to understand that the child's recovery depends upon her own watchfulness and care.

The osseous deformities can be prevented, to a certain extent, by hindering the child from walking while the bones are still soft. The bowing of the legs is often owing to the child's getting upon his feet before the bones have become sufficiently consolidated to bear the weight of the body. In these cases light well-padded splints which project below the feet will be the best safeguard. When the ligaments of the joints are loose and weak, the joints may be much strengthened by a well-fitting elastic support.

After the tenderness of the body has subsided, the child should be well shampooed, especially along the spine, both morning and evening.

With regard to the complications—diarrhoea and pulmonary catarrh must be treated upon ordinary principles. A good flannel bandage very much diminishes the tendency to relaxation of the bowels, and is of further value in retarding the too rapid descent of the diaphragm, and so in diminishing to a certain extent the recession of the chest-walls during inspiration. If convulsions occur, search must be made for any local disturbance which may have set them up. This is often some form of gastrointestinal irritation. It must be remembered that the abnormal sensitiveness of the nervous system in this complaint renders the patient peculiarly responsive to such impressions, and that the beginning of the infectious fevers and the agitation of whoop-

ing-cough are more likely than in a more healthy child to be followed by nervous phenomena. Rotatory cervical spasm is often quickly cured by a few nightly doses of rhubarb and soda, at the same time reducing the quantity of starch and other acid-making matters in the food. The same may be said for the milder cases of tetany. The more severe form of the latter disease yields only to the measures which are effectual in subduing the rickety condition, viz. wise feeding, fresh air and tonics. It is, however, often obstinate, and may only subside as the original disease declines. Chloral hydrate and other nerve sedatives are of small value in reducing the spasms (see CONVULSIONS IN CHILDREN; and HEAD-NODDING OF INFANTS). Laryngismus stridulus is often cured at once by bathing the whole body twice a day with water of the temperature of 70° F. while the child sits in hot water. At the same time it is well to remember that these attacks are usually significant of the presence of adenoid vegetations in the naso-pharynx, and are apt to return unless the vegetations be removed.

The moment scurvy is detected, the child's diet should be revised. He should be given plenty of fresh cow's milk, and this may be thickened once or twice a day with a well-boiled potato. For medicine, half a grain of quinine dissolved in a teaspoonful of fresh lemon-juice can be given three times a day. If the gums are spongy, Cheadle's recommendation of the glycerines of tannic acid and carbolic acid (fifteen drops of each in an ounce of water) is useful, applied with a soft brush. The legs, if tender, should be supported by a soft cushion behind the knees. If the epiphyses have separated light splints must be applied.

RICKETS, SCURVY.—See RICKETS, p. 1429; and SCURVY, p. 1469.

RIGIDITY (*rigidus*, cold, frozen, stiff). —SYNON.: Fr. *Rigidité*; Ger. *Starrheit*.—This term implies the existence of a more or less fixed condition in parts that ought to be freely movable. It is a state met with principally in the limbs, where it is dependent upon certain unnatural conditions of the joints or of the muscles, either separately or in combination. It may, however, occur in the trunk as a whole, or in the neck, owing to the existence of tetanic or tonic spasms in muscles, due to one or other of various causes. The valves of the heart, and the arteries, when stiffened by fibrosis, are said to be rigid. Again, it is a term commonly applied to a condition of the 'os uteri' during parturition, in certain women, in whom the orifice of the womb does not dilate coördinately with the increase in force of the uterine contractions. The term is also sometimes used in connection with the features. Marked rigidity of a limb at this or that articulation often results from joint-disease. Perhaps more frequently, however, rigidity in a limb is primarily dependent upon altered functional or nutritive conditions of its muscles, which may or may not be associated with actual paralysis implicating the same parts.

Numerous cases exist in which, without the existence of paralysis, or with a comparatively small amount of it, tonic spasms occur in the muscles of a limb, so as to entail rigidity (see

SPASM). This may be met with, for instance, in hysteria, and in the early stages of some spinal diseases, more especially in primary lateral sclerosis, or in the form of paralysis that goes with Pott's disease.

More frequently still, however, rigidity is found in association with distinct paralysis. For many years a distinction has been made between two kinds of rigidity associated with paralysis; the one of which, known as 'early rigidity,' is apt to supervene with or a few days after the onset of a cerebral or spinal paralytic affection; while the other, known as 'late rigidity,' comes on rather in old cases in which mere paralysis with flaccidity of muscles may have been previously present. The former is now believed in many cases to have a tendency to pass into the latter form; and where this becomes well-developed, it is commonly associated with a secondary or with a primary sclerosis of the corresponding lateral column of the spinal cord, even though the initial paralytic lesion may be in some portion of the motor tract of the opposite cerebral hemisphere (see SPINAL CORD, Diseases of). In 'early rigidity' we have to do with mere functional changes in the muscles, and the condition itself of rigidity is not constant; it intermits from time to time; during the day, and commonly disappears during sleep. But in 'late rigidity,' associated with extensive secondary degenerations in the spinal cord, the nutrition of the nerves, as well as of the muscles and their tendons, appears to suffer, and that, for the most part, in an irremediable manner. This more severe condition of rigidity is associated with actual shortening of muscles or tendons, and in this stage but little, if any, difference exists between the degree of rigidity of the limbs by night and by day. See MOTILITY, Disorders of.

H. CHARLTON BASTIAN.

RIGOR.—SYNON. : Shivering Fit; Fr. *Frisson*; Ger. *Schüttelfrost*; *Fieberfrost*.

DEFINITION.—A group of phenomena the essential constituent of which is a series of clonic muscular contractions accompanied by a rise of temperature, and by various subjective sensations, chiefly of cold and heat.

DESCRIPTION.—A rigor generally commences with a sensation of chilliness referred to the back or the extremities, accompanied by a feeling of wretchedness and by headache. The extremities are cold, blue and pinched, and their surface-temperature is lowered. The patient usually sits or lies huddled up, heaping coverings on himself in his endeavour to keep warm. The respirations are shallow and hurried, the pulse small and rapid. Nausea is frequent and actual vomiting may occur. The internal temperature of the body is raised and the surface of the trunk may feel unduly hot. After this condition has lasted a varying period the actual rigor occurs. This consists of a series of involuntary clonic contractions, commencing in the muscles of the lower jaw, and causing chattering of the teeth. The clonic contractions then spread to the muscles of the trunk and limbs, and may cause sufficient movement to shake the bed or chair occupied by the patient. These contractions last for a period varying from a few seconds to two hours, and are succeeded by a general flushing of the skin, accompanied by a feeling of heat and thirst and by copious perspiration. The pulse becomes full and bounding, and

the temperature begins to fall. The headache continues, but consciousness is rarely lost during the attack, though mental processes are interfered with, irritability being often marked at the onset of the attack.

The rise of temperature which accompanies the occurrence of rigors is always rapid, but the actual degree of pyrexia does not appear to influence the severity or duration of the rigors themselves. The rigors do not occur at the maximum temperature, but usually, when the temperature has reached about one-half to two-thirds of its maximum. The rigor itself may be single, or may occur as a series of shivering fits following quickly on one another. Death rarely, if ever, takes place during a rigor.

ÆTIOLOGY AND PATHOLOGY.—In the phenomena above described we recognise the action of the central nervous system. The vaso-motor, respiratory, vomiting and thermotactic as well as the motor and psychical centres are involved. The phenomena are not to be explained by the existence of any special centre concerned with the production and control of rigors, but seem rather to indicate the existence of some toxic agent or agents in the circulation, causing inhibition of the highest—i.e. controlling—function of various cerebral centres. Thus, in the rise of temperature, shivering, vomiting, altered pulse and respiration and altered sensations we see interference with centres we have reason to locate in very different parts of the central nervous system. The similarity rigors bear to one another, their usually short duration, and the fact that paralysis does not follow the muscular movements indicate that we have to deal with a withdrawal or suspension of normal inhibition from, rather than a direct stimulation of, the various centres. Pyrexia itself cannot be assumed to be the direct cause of the rigors, nor can mere change of temperature, for, although we find some of the phenomena, such as the sensation of cold, and the transient shiver as the result of sudden exposure to cold, yet true rigors do not occur when the temperature rises slowly, nor when it falls rapidly.

A consideration of the conditions under which rigors occur enables us to distinguish two main classes of agents causing them: (1) Those in which we must assume the presence of certain poisons in the general circulation—*toxic rigors*; and (2) those in which the rigor appears to depend on the existence of some peripheral mechanical irritant which acts on the sensory nerves, chiefly on those distributed to the mucous membranes; these may be distinguished as *sensory or algæic rigors*.

(1) *Toxic rigors.*—It is probable that several toxic agents are capable of giving rise to rigors, since rigors are common to so many different acute specific diseases. The toxic agents we assume to be the cause of these rigors may be elaborated within the body itself, as in the case of the virus of an acute specific disease. In the case of malaria the occurrence of rigors corresponds to the stage of sporulation of the parasite in the blood (see MALARIAL DISEASE). When rigors occur in the course of diseases attended by suppuration the rigors do not always coincide with the formation of fresh foci of pus. Repeated rigors may occur with a single focus of suppuration. In those cases where transfusion with normal saline solution has been followed by rigors it is probable that some chemical

substances formed within the body are dissolved and carried to the central nervous system by the bloodstream, and in the cases where rigors have followed the introduction of antitoxin into the body a similar sequence of events may likewise be assumed.

(2) *Sensory rigors*.—In some healthy individuals a sudden exposure of the skin to cold, or the mere passage of urine over the mucous membrane of the urethra, is accompanied by a transient shiver representing in miniature the clonic muscular contractions of a rigor.

As the result of more intense stimulation of the nerves of the mucous membrane we produce phenomena approximating a true rigor. Thus, directly after the passage of a catheter in some people a marked shiver may occur, or there may be a definite rigor, with rise of temperature and the other symptoms of a true rigor, occurring a few hours after interference with the urinary passages. A condition analogous to this form of rigor is not infrequently observed soon after the act of parturition, and has no grave significance. Differing from these in the fact that they are attended by severe pain are the rigors due to the presence of urinary or biliary calculi, and occasionally of foreign bodies or fecal masses in the intestine. The rigors which occur under these conditions are probably due either to the reflex action of the nervous system in response to a painful impression, or to toxic agents introduced at the site of mechanical irritation or derived from the tissues which have been injured. If this second view be correct, all causes of rigors may be included in one class—the toxic agents. That this is unlikely is shown by the fact that in the case of rigors following the passage of a catheter or after injuries to the urethra, the rigors may actually occur before the catheter has been withdrawn, or while urine is first passing over the urethral lesion, and before time has been given for the absorption of any toxic material. In many cases of rigors accompanying the passage of calculi, there has been found no evidence of laceration, ulceration, or other injury to the urinary or biliary passages, and the frequency of intestinal ulcerations, and the rarity of rigors traceable to an intestinal lesion, would all seem to negative the view that such rigors were due to a toxic absorption.

Although rigors may be produced as the result of toxic or of sensory stimuli, their occurrence depends very largely on the personal susceptibility of the individual. In children rigors are rare because their place is taken by convulsions; and in epileptics the acute specific diseases are often ushered in by a series of epileptic attacks in place of a rigor.

SIGNIFICANCE OF RIGORS.—Rigors occurring at the onset of one of the *acute specific diseases* have little or no significance. They commonly occur at the onset of acute pneumonia, variola, scarlet fever, and erysipelas; but they may also usher in the onset of other acute *inflammatory processes* as in pleurisy, pericarditis, and peritonitis. There is nothing distinctive in the rigors occurring in these different diseases, though in some, as in acute pneumonia, there is usually one severe rigor, while in others, as in pleurisy, a series of slighter rigors occurs; yet in neither case are they always present, nor can a series of slight rigors serve to negative the diagnosis of acute pneumonia. A rigor occurring in the course of an acute specific disease may have a much graver significance: it may indicate

the formation of some focus of suppuration or the occurrence of some serious complication such as the supervention of pericarditis in the course of pneumonia. In *enteric fever* rigors may be met with either at the onset of the disease or during its course. The initial rigors are rare. Occurring in the course of the disease rigors may indicate the formation of foci of suppuration, or may be the result of intestinal irritation, of which constipation is the most common cause. Osler asserts that rigors may be due in some cases to the too free use of the antipyretics derived from the coal-tar series. Abercrombie has pointed out that rigors in enteric fever, occurring independently of perforation or peritonitis, are commonest in women, and may sometimes be traced to emotional causes.

At the commencement of an attack of *paroxysmal hæmoglobinuria* slight rigors with a rise of temperature may take place. Rigors may accompany the formation of *thrombi* in the veins, or may occur with the formation of an *infarct*, even if this be not infective. In *pyæmia* the rigor generally occurs by day, and there is rarely more than one in the twenty-four hours. Although there may be large numbers of suppurating foci, there is no relationship between them and the number of rigors. In *infective endocarditis* rigors are not uncommon. They do not of necessity indicate that there is a suppurating infarct. Rigors are met with in cases where suppuration occurs in connection with veins, especially in the cerebral, hepatic and uterine veins.

The formation of *abscesses* in the substance of any organ, and the occurrence of *infective inflammation* of a mucous membrane, as in pyelitis, may be accompanied by severe rigors. In cases of *poisoned wounds*, such as may result from infection while making a *post-mortem* examination, rigors may occur without any evidence of the formation of any focus of suppuration.

TREATMENT.—Rigors themselves do not call for any treatment apart from that of the disease causing them. With the object of making the patient as comfortable as possible during the stage of shivering, he should be put to bed and kept as warm as possible, being wrapped in warm blankets, with foot-warmers, and hot drinks containing a diffusible stimulant, such as alcohol, may be given. In this stage, when all the cutaneous blood-vessels are in a condition of spasmodic contraction, such vaso-dilators as nitrite of amyl, nitroglycerin, tetrannitrate of erythrol, and nitrite of sodium have been employed. During the hot stage tepid sponging, or even cold sponging, may prove grateful; and barley-water or soda-water with fresh lemon in it will be found to give welcome relief to the patient's symptoms. In malarial rigors quinine should be given hypodermically. *See* MALARIAL DISEASE.

ARTHUR F. VOELCKER.

RIGOR MORTIS (Lat.: The stiffness of death). **SYNON.:** Fr. *Rigidité Cadavérique*; Ger. *Todtenstarre*.—The stiffening of the muscles after death, due to coagulation of their plasma. *See* DEATH, Signs of.

RINGWORM.—*See* TINEA TRICOPHYTINA.

RIOLO, in Italy, near Bologna.—Chalybeate, sulphurous saline waters. *See* MINERAL WATERS.

RIPPOLDSAU, in the Black Forest, Germany.—Mixed iron waters. See MINERAL WATERS.

RISUS SARDONICUS or **SARDONIUS** (*risus*, a laugh; and *sardonius*, connected with, or caused by, the herb *sardonia* or *sardoa*, that is, belonging to Sardinia).—A peculiar expression of the face, in which the features are distorted by spasm of the muscles, so as to present the appearance of a painful grin or laugh. It is usually observed in tetanus. See TETANUS.

ROBURITE, Poisoning by.—See DYNAMITE.

RODENT ULCER.—SYNON.: Fr. *Cancroïde*; Ger. *Epithelialkrebs*.—Rodent ulcer must be recognised as a kind of tumour; but its exact position among other forms of new-growth is still not absolutely decided. Hence, in this work a special article is devoted to its consideration. Most authors agree in classing it among the epitheliomata—a conclusion which the accumulated evidence of recent years tends to make practically certain.

CLINICAL CHARACTERS.—*Naked-eye appearances*.—A distinguishing feature of most rodent ulcers is the fact that ulceration follows *pari passu* with new-growth, the result being that, as in the case of lupus, instead of the formation of a swelling or tumour, an actual diminution of the size of the part occurs. Another characteristic of the disease is, that while it often makes its appearance at a period of life which might be considered early for an epithelioma, it runs a course of extreme chronicity, and rarely, if ever, affects the lymphatic glands. Many cases last for twenty or thirty years, interfering but little with the general health, and at times in part undergoing a process of feeble cicatrization. In one case observed by the writer the cicatrix was rather extensive, and had stood the test of a considerable period of time.

Rodent ulcer begins as a pimple, usually on the upper part of the face, and most frequently on the side of the nose or about the eye. It is occasionally met with in other parts of the face and of the body. After this has remained quiescent for a long time, perhaps years, ulceration usually occurs, and continues to spread with great slowness, involving in its course every structure that it meets. In rare cases, however, there is no ulceration, the characteristic margin of the growth surrounding a thin uniformly smooth cicatrix. Thus in time huge caverns are excavated in the face; the eye-ball may be destroyed; the nose and upper jaw may disappear; and not infrequently, if the disease reach the forehead, the dura mater is exposed, and the brain is seen pulsating at the bottom of the cavity. The appearance of the ulcer is characteristic: the surface is glistening, and is covered with very imperfect granulations; it has an uneven floor, and is mottled with yellow and red; the margin is very slightly raised, and somewhat indurated, has a purplish-pink colour, and is often considerably undermined. The discharge is thin and purulent. Capillary hæmorrhage not infrequently occurs, but more severe bleeding is rare. A section through the edge shows the narrow margin of new-growth,

in which alone the characteristic structure is to be made out. Death may occur from old age or other causes independent of the disease; from an attack of erysipelas or meningitis, or from marasmus induced by the constant worry and discharge.

MICROSCOPICAL APPEARANCES AND PATHOLOGY.—Many tumours which approach somewhat nearly the condition above described will be found on examination to possess the structure of a lobular epithelioma (see CANCER); but the most typical ones will usually exhibit something like the appearance represented in Plate IV. fig. 3, p. 244. Beneath the epidermis, and embedded in a varying amount of stroma consisting of more or less well-developed fibrous tissue, are large, roundish, and irregular masses of densely packed epithelial cells of small size, the circumferential ones taking an oval shape, while the deeper ones are circular. There is, as a rule, no tendency to the formation of globes; but, in some cases which have run a typical course, imperfect nests have been found. The so-called *prickle-cells* are, as far as the writer has observed, never seen. The cells are smaller than those usually met with in an epithelioma, and suggest the origin of the growth from the sweat-glands, a view which is favoured by the fact that the epithelial masses occasionally assume a more or less distinctly tubular arrangement. Strenuous advocates are found in support of, and in opposition to, this theory of the primary source of rodent ulcer, and the same may be said of other hypotheses, such as that it starts from the hair-follicles or the sebaceous glands; but, in default of stronger evidence than is at present forthcoming, it would be unwise to dogmatise upon the question.

PROGNOSIS.—The prognosis in a case of rodent ulcer may be implied from what has been said of its clinical features, course, and terminations.

TREATMENT.—The obvious treatment is free removal by the knife in the early stages. The method of scraping with a sharp spoon, which is not infrequently adopted, is not so likely to reach the limits of the disease, and does not seem to have sufficient theoretical or practical evidence to support it. C. H. Moore was a strong supporter of the plan of removing even very large ulcers; he was in the habit of proceeding with the knife as far as prudence would allow, and applying chloride-of-zinc paste to any parts it was considered unsafe to cut away. This treatment in his hands and in the hands of other surgeons has been followed by very marked success. R. J. GODLEE.

ROHITSCH, in Styria (Austria).—Acidulated, sulphated waters. See MINERAL WATERS.

ROISDORF, in Germany.—Mixed alkaline table-waters. See MINERAL WATERS.

ROMBERG'S SIGN.—An inability to stand steadily when the feet are close together and the eyes shut. See TABES DORSALIS.

ROME, Central Italy.—Moderately warm, moist, fairly calm winter climate. Mean winter temperature, 45° to 50° F. The air is damper than that of the Riviera. See CLIMATE, Treatment of Disease by.

ROMEGNO, in the Val Sugana, in the Austrian Tyrol.—Arsenical sulphate-of-iron waters. See MINERAL WATERS.

RÖMERBAD, in Styria.—Thermal waters.
see MINERAL WATERS.

RÖNTGEN or X-RAYS.—In December 1895 Professor Röntgen announced in a communication to the Würzburg Physico-Medical Society the discovery of a new form of radiation. The first paragraph of his paper is as follows: 'If we pass a discharge from a large induction-coil through a tiffiori, or a sufficiently exhausted Leonard's or Crookes', or other similar apparatus, and cover the tube with a somewhat closely fitting mantle of thin black cardboard, we observe that a paper screen covered with crystals of barium platino-cyanide lights up brilliantly, and fluoresces equally well, whether the treated side or the other is turned towards the discharge tube; fluorescence is still observable 2 metres away from the tube. It is easy to convince one's self that the cause of the fluorescence is the discharge from the apparatus and nothing else.'

So thoroughly did Röntgen investigate the properties of these new and unknown rays that his original communication contains almost all that is even yet known about them. He called them the X-rays.' In a Crookes' tube after a certain degree of exhaustion, wherever the cathodal rays strike solid matter, these X-rays originate. In the well-known X-rays tubes the cathode or negative terminal is concave, and the cathodal rays coming from it converge to a point or focus. At or near this position is placed the positive terminal (usually of platinum) called the anode. Thus the cathodal stream impinges at its narrowest part on the anode, and in this manner the X-rays originate from a comparatively small surface or point, and so can cast sharp shadows of objects upon a screen or photographic plate. The X-rays have the following properties:

1. They proceed in a straight line—they cannot be refracted or diffracted, and can only be reflected to a small extent, and then as a *scattered* reflection.
2. Ordinary matter is opaque to them in proportion to the atomic weights of its constituents. If equal volumes of all the elements were taken the lightest would allow most of the X-rays to pass through, and so on in the order of the atomic weights. It therefore follows that our own bodies, and all organic matter, are comparatively transparent to X-rays.
3. They have the power of discharging electrified bodies (this is also the case with violet rays).
4. They act on a photographic plate like light; it seems probable that they are due to disturbances in the ether similar to the ordinary waves producing the visible spectrum, only of extremely short wavelength.
5. They cause certain crystals to fluoresce. The best for that purpose are those of platino-cyanide of barium and platino-cyanide of potassium. Tungstate of lime and other substances fluoresce less brilliantly. The usual screens in the market are of cardboard spread over with crystals of the platino-cyanide of barium.

The great practical importance of these rays is their utility in medicine and surgery. So far they seem to serve no useful purpose in any other domain.

The apparatus necessary for the production of X-rays suitable for medical and surgical purposes is

very varied, and here only a very general description can be given.

Induction-coil.—For all-round work a coil giving a ten-inch spark is sufficient.

Current.—From 12 volts (which is given by an accumulator of 6 cells) up to 100 or 200 volts from the mains can be used, depending upon the kind of interrupter employed.

Interrupter.—The electrolytic or Wehnelt is the most effective, but is unfortunately somewhat uncertain, and is apt to destroy the tubes. The mercury-jet break is good, and a rotatory mercury-break, with a blade on an inclined shaft, gives excellent results, and is completely under control, giving the most effective output from the coil according to the speed of rotation with any voltage. A small sliding resistance adjusts the speed of rotation to suit the voltage.

Tube.—There are a good many good tubes in the market. The chief essentials are: (1) that the X-rays should come from a fine point on the anode; and (2) that the tube should possess some arrangement for reducing the vacuum if it gets too high. It is necessary to have several tubes, some with a high vacuum for use in deep structures, such as the hip-joint, and some with a low vacuum for examining the extremities and for therapeutic purposes.

It is advisable to have the whole tube surrounded by some non-conducting material opaque to X-rays, with an opening in it. The opening should be situated opposite the anode at a point where the fluorescent screen has its maximum brilliance when held close up against the glass. The object of this covering is to cut off stray X-rays from the glass of the bulb which fog the photographic plate and prevent a sharp image. The definition is thus much improved. Another advantage is that the operator can keep out of this diverging cone of X-rays, and so avoid the injuries resulting from too long and continuous exposure to the radiation from the tube. The most effectual way of covering a tube is to bury it in red-lead in a wooden box or porcelain or glass vessel and scoop away as much as is necessary at the right place, and with a small cylinder of paper prevent the 'banked-up' powder from falling in. It is more convenient to place it in a box which has been lined by about half an inch thickness of a mixture of red-lead and the white-lead of the shops—which hardens in time and yet is not brittle. The tube can be fastened to the lid by elastic bands, and an opening in it will act as a stop or diaphragm. If desired, smaller 'stops' can be dropped into this one and so a very narrow cone of X-rays obtained giving definition over that area correspondingly sharper and with much less general fog. This method of working the Crookes' tube will be found to be of great practical advantage in dealing with deep structures, and especially with cases of stone in the kidney, bladder, or ureter.

Screen.—The most useful is made by coating a piece of cardboard with crystals of platino-cyanide of barium.

Photographic Plates.—It is important that these should have a *thick* coating of emulsion. This will render short exposures effective, because X-rays pass so readily through the emulsion that, the thicker this is, the more distinct is the result. The support may be glass or celluloid or paper; the material does not seem to affect the 'speed' to any extent.

Röntgen Rays in Surgery.—At first the mere fact that the bones, bullets, or a fragment of needle could be revealed was so astonishing that for a time surgeons were quite content to get a single photograph, and considered it a valuable aid. As the work extended, and as operations based upon such photographs followed, it became evident that something more than a single picture was required. A moment's consideration will show why this is so. The X-ray photograph is not taken under the ordinary conditions with camera and lens: it is simply composed of shadows. Lay a large piece of white paper upon a table in a darkened room, place upon it any object or objects; hold above them a lighted taper or candle at about the distance an X-ray tube would be placed, so that the shadows will fall on the paper; and observe the shadows cast by the light from the taper—what a variety of different shadow-pictures can be produced by moving the light to different positions. The only real difference between such a picture and one produced by the X-rays is that these rays get through many of the objects themselves, and then not only cast a shadow of their outline but even of their very interior structure—e.g. the bones in good skiagrams have not only their outlines shown but also the cancellous structure. The desire to have these skiagrams properly interpreted led to methods of *localisation* being devised. Of these there are many. The writer described a method of precise localisation by means of Röntgen Rays in the *British Medical Journal* (January 1, 1898, and December 3, 1898) which is simple and extremely accurate—so much so that it has been used to locate minute foreign bodies in eyeballs and orbit with most satisfactory results. It is based on geometry. The three co-ordinates of any point can be obtained by measurement only—no calculations being required. It has the further advantage that the two skiagrams are stereoscopic and can be seen in relief, and the position of the bones, bullet, &c., seen in their true relations.

Stereoscopic Skiagraphy.—It appears likely that this method, which is at once simple and effective, will replace all the more intricate and troublesome methods for localisation (except in ophthalmic cases). The tube is first placed in the usual way—as if a single picture only was to be taken. After this is taken, the first plate is replaced by a fresh one, and the tube is displaced six centimetres (the average distance between our eyes when moderately converging) to one side, and another photograph is taken. The resulting negatives on a casual inspection seem very much alike, but when viewed in a Wheatstone stereoscope they combine and produce a single image of extraordinary brilliance; this picture is seen to possess the third dimension, viz. depth, and a most reliable and realistic image results. Of course it is absolutely essential that the observer should himself possess correct binocular vision.

The point of importance in taking these pictures is that when the tube is displaced, an imaginary straight line, connecting the two positions of the tube shall be parallel to one edge of the photographic plates. In order to ensure this there are two plans. (a) If the tube is placed above the patient, then the part to be skiagraphed must rest on a piece of stretched parchment (such as is used in the best drums), and a wire must be stretched along one side near and parallel to the edge of the

parchment, and the bar along which the tube-holder slides must be adjusted to be parallel to this wire. The photographic plate protected in the usual way in black-paper wrapping or envelopes is placed beneath the parchment, so that the plates can be changed without disturbing the position of the patient (a most essential point in order to produce correct stereoscopic pictures). The wire leaves a white line on the negatives, and this of course comes out a black line on the prints. These are then cut to the black line and mounted accordingly. They can then be viewed in a Wheatstone reflecting stereoscope, or for those who have acquired the power they can be viewed by converging the eyes upon the negatives (immediately after development), or upon the prints, and seen as a single image in striking and reliable relief.

The apparatus need not be complicated. The parchment should be stretched over a frame large enough to admit the largest photographic plate that is likely to be used, protected in the usual way in paper envelopes. This simple arrangement can be applied to a couch, or made separately in the form of a stool. It enables the part to rest on the parchment undisturbed, while a fresh plate can be exchanged for the first one. Piano-wires can be stretched across for purposes of localisation.

(b) A still more simple plan is to have a couch like a camp-bed, with canvas or fine strong twill. The tube can then be placed on a holder beneath, or in a box with red-lead, as described above, and can be arranged to slide easily up and down, or across on wooden bars provided for the purpose. In this way all the desired positions for the tube can be obtained. The patient can lie on this couch and not be disturbed, while with a fluorescent screen the surgeon explores the whole body. For photographing, the tube is first placed below the part, and a photographic plate is laid upon the patient; one edge of the plate is placed parallel to the transverse edge of the tube-holder, so that when the tube is displaced to one side (to get stereoscopic skiagrams) it moves in a plane parallel to the edge of the photographic plate. The advantages of a couch like this are numerous. In the first place the patient is not perturbed by the tube hanging over him. The surgeon can by means of the screen decide exactly what part he wishes to photograph, and can place his plate there. He can even watch how the tube is really working by looking through the plate while the photograph is actually being taken. When using large plates there is no risk of breakage or having the plate marked by pressure. Altogether the plan seems the best and simplest of all. Further, a couch of this kind can be used as an operating one, and without any difficulty if required during the operation the surgeon could examine the patient with the fluorescent screen.

Stereoscopic Fluoroscope.—This instrument enables an observer to see the X-ray shadows upon the fluorescent screen *in relief*. In addition to the marked advantage of seeing through the patient in this way, if an object opaque to X-rays, such as a knife, needle, or probe, be employed, it can be used to reach or touch any object visible in the screen-picture. At present the difficulty in the use of this instrument is to be able to get the patient conveniently into the necessary position between the two tubes and the eye-holes in the revolving shutter.

It is not necessary to detail the apparatus fully here; suffice it to say that there are two tubes

placed side by side as close to each other as possible. These by a suitable break and commutator in the secondary circuit of an induction-coil are made to work alternately. Opposite these tubes are two eye-holes for the observer, with a revolving eclipsing shutter, so that each eye only sees the shadow of the one tube, and this taking place alternately, and repeated ten times or more per second, the shadows of an object on the interposed screen, that each of the observer's eyes receives, become a continuous impression, and these are fused by the brain in the usual way, and a 'Stereoscopic shadow' is seen. The value of this instrument will be considerable in the examination of the thorax, where the movements during respiration lessen the definition in photographs. In the examination of fractures, dislocations, or lodged foreign bodies, the Stereoscopic fluoroscope will prove of great practical value, as the shadows of the parts are seen standing out in solid relief, in relatively correct positions. And still more practical is the fact that any object that is seen in this way can be touched by the observer or he use a metal probe, or knife or forceps, since the shadow of the instrument is seen in relief and seen under the same optical conditions as the part of the patient under examination.

We may now sum up the advantages of the Röntgen Rays in surgery, with hints as to procedure in special cases.

1. *Normal.*—It is of interest to have skiagrams of normal parts, as it enables the structure of the body to be seen under new conditions. In young patients an accurate knowledge of the amount of ossification can be acquired.

2. *Fractures and Dislocations.*—Diagnosis can be made painlessly, even when parts are much swollen and painful.

3. *Lodgment of foreign bodies.*—All the metals and glass can be detected.

4. *Calculi.*—In the bladder, ureter or kidney calculi can be detected, provided the patient be not too stout, or the calculus too small. The usual law of the atomic weights, deciding the opacity of a body to X-rays, comes into play here, and given equal volume, the calculus with the greatest atomic weight will be the most opaque, the most easily differentiated from the surrounding tissues, and therefore the most easily detected. Another arrangement that helps towards success in these difficult cases is to regulate the patient's breathing while the photograph is being taken. If possible arrange to turn on the current, and only to expose while the patient holds his breath in the same phase. By this procedure the kidney, which is displaced during the period of breathing, will occupy the same position while the photograph is being taken.

There are automatic arrangements made for this purpose, but these are necessarily complicated. A simple method is to have a long light piece of wood fastened to an elastic band put round the patient's chest; a pin put through the strip of wood is supported from a stand. If a scale is placed near the other end of this indicator, after a few trials the patient will be able to regulate his breathing, so as to bring the point of the indicator always to the same position on the scale, and keep it there by holding his breath for 20 to 40 or more seconds if necessary.

Ophthalmic Surgery.—X-rays have proved of extreme value in this branch of surgery. The writer

has detected and located by their means steel, iron, brass, copper, silver, lead, and glass in the eye and orbit. The method to be followed in precisely localising some of these particles, which are extremely small, is somewhat difficult, but if due pains are taken the result is always correct.

Teeth.—The best plan is to wrap a small piece of a photographic film in black needle-paper, and then enclose it in a piece of gutta-percha tissue, which can be sealed with chloroform. This can then be introduced into the patient's mouth, and held closely up against the part to be skiagraphed. The Crookes' tube is then placed in a suitable position. The patient must have his head supported to avoid movement.

Röntgen Rays in Medicine.—*A. Diagnostic.* Gradual progress is being made, but meantime the aid that the X-rays afford the physician is comparatively limited.

Aneurysm of the aorta in the chest can be seen on the fluorescent screen and photographed. It has a sharply defined border, projects from the general mediastinal shadow, and can be seen to pulsate.

Tumours in the chest are shown, but no clue to their nature is given, they simply cast a darker shadow than lung or pleural fluid. As a rule pleural fluid gives a much less distinct edge than a mediastinal or pulmonary growth.

Abscess in the lung and tubercular lesions are less transparent than the normal lung, except in the cases of large cavities, easily recognisable by other means.

Abscess on the surface of the liver has been detected.

The movements of the diaphragm on the two sides can be studied and contrasted when watched on the screen.

The abdomen is very difficult to examine by means of X-rays. With the exception of gaseous distension of the stomach, renal calculi, and metallic foreign bodies which can be detected, little information can be obtained.

B. *Therapeutic.*—Accidentally it was discovered that sometimes when a patient was long exposed to X-rays, a more or less destructive inflammation of the skin nearest the tube took place, and in severe cases extensive and deep sloughs occurred. At the present moment it is not quite certain if the X-rays are responsible for these injuries, or whether it may be due to some accompanying radiations. The radiations from a Crookes' tube are necessarily complex, and at present these have not been satisfactorily differentiated. It naturally came about that this destructive action was used to try and destroy the germs in certain diseases, just as one ordinarily tries to cure lupus by scraping, or by the action of the cautery, or caustics. The results in lupus have been decidedly encouraging. An X-ray tube with a low vacuum, or, more correctly, a tube which has a very short alternative spark-gap resistance, seems to act better than a 'high' or, as the Germans express it, a 'hard' tube. Repeated exposures have to be given, and the tube need not have too much energy passed through it, so as to heat it. In course of time favourable results ensue. It is not yet established, however, that this method is markedly superior to some of the usual methods of dealing with lupus. It is said that rodent ulcers have been cured by means of X-rays.

Depilatory effect of X-rays.—In several cases successful results have followed exposure to X-rays,

but one must be careful to ascertain the limits of safety, that is, just enough exposure to destroy the hairs, and yet cause no destruction of the skin itself. It seems that as yet there is no exact certainty about this procedure, as in some cases successful depilatory action results, while in others it is disappointing. In most cases the growth of hair is not arrested permanently, but possibly repeated and well-timed application of the radiations from the X-ray tube might prevent growth recurring. The tubes most useful in producing destructive changes are of low vacuum. The exposures have to be long and repeated frequently. *See also* p. 376.

That the X-rays have been of immense value to medical science is unquestionable. It is only a short time since they have been discovered, and we are yet only imperfectly realising their possibilities.

JAMES MACKENZIE DAVIDSON.

ROSACEA.—*See* ACNE ROSACEA.

ROSEOLA.—Fr. *Roséole*; Ger. *Roseola*.—This is a term more used in the past than the present for patchy erythema, in which the tint is less bright than usual, a trivial distinction which scarcely justifies its continued existence. If retained at all, it would be best restricted to the symptomatic eruptions seen in various serious constitutional conditions, as in the early stage of syphilis, in leprosy, and less constantly in variola before the more characteristic rash, and in vaccinia, cholera, diphtheria, malaria, spinal meningitis, and enteric fever.

A so-called idiopathic roseola is sometimes seen in young children, chiefly in the spring and autumn—a disordered alimentary canal, especially during dentition, being the most common ætiological factor. In such cases there may be an elevation of temperature of several degrees, with other febrile symptoms, but without catarrh, and lasting for a few hours only as a rule. The eruption, which is rose red, varies much in shape. There may be patches the size of the end of the finger, faint papules, circles, or gyrate outlines. These come out in any part of the body or nearly all over, fading perhaps at one part and appearing at another, the whole process lasting a few days. *See* FEBRICULA.

TREATMENT.—But little treatment is required for so transitory an affection, which is chiefly interesting from a diagnostic point of view. Any disorder of the alimentary canal should be corrected by a mild mercurial purge; and every likely cause of irritation, either in the gums or elsewhere, should be searched for and removed if possible.

The roseola symptomatic of the grave disorders enumerated requires no special treatment, the serious constitutional condition claiming the whole attention.

H. RADCLIFFE CROCKER.

ROSE-RASH.—A popular name for roseola. *See* ROSEOLA.

RÖTHELN.—The German synonym for rubella; frequently employed by English practitioners. *See* RUBELLA.

ROUND-WORMS.—*See* ENTOZOA.

ROYAT, in France.—Muricated alkaline waters. *See* MINERAL WATERS.

RUBBING-SOUND.—A synonym for friction-sound. *See* PHYSICAL EXAMINATION.

RUBEFACIENTS (*ruber*, red; and *facio*, I make).—A class of counter-irritants which produce simple redness of the skin. *See* COUNTER-IRRITANTS.

RUBELLA.—SYNON.: German Measles; Fr. *Rubéole*; Ger. *Rötheln*.

DEFINITION.—A specific infectious eruptive fever. The rash appears on or after the first day of the illness, beginning on the face in rose-red spots, extending next day to the body and limbs; it subsides with the fever on the third day; and is not preceded or accompanied by catarrh, but is associated with enlargement of the lymphatic glands in the neck.

ÆTIOLOGY.—Propagated by contagion, rubella occurs in epidemics, often of limited extent, commonest in spring and early summer. The period of incubation is mostly over a fortnight, the extremes being from ten to twenty-one days. Hence arises a difficulty in tracing the source of infection, increased by the slight and transient symptoms which permit the illness to be entirely overlooked, the patient consequently mixing freely with others. One attack is not preventive of a recurrence. Very young infants seem less susceptible than older children; a child at the breast has been known to escape when the mother and other children in the family have been attacked; adults not infrequently suffer; sex makes no difference. A recrudescence of the rash from the third to the sixth day is sometimes seen.

SYMPTOMS.—Slight headache or giddiness is felt, with aching of the back or limbs, chilliness, and a little sore-throat, for twelve hours or a day before the rash appears. Very often the rash is first seen with surprise, as the feeling of illness has passed or may have escaped notice. Enlargement of the superficial cervical glands, especially in the posterior triangles of the neck, is an early sign, often developing a week before the rash appears, and most marked in children. There is redness of the fauces and uvula, less mottled than in measles, not so intense as in scarlet fever; the tonsils are a little swollen; there is no ulceration. Sometimes an odour, as in measles, attends the rash. The eyes are suffused, but there is little or no coryza; the lids are somewhat swollen and irritable; the face and the cheeks may be flushed before the appearance of the spots. The rash is first seen behind the ears, around the mouth and about the nostrils; it consists of bright red, raised, rounded spots, with clear skin between them, but they soon coalesce; not grouped as in measles, the spots are more prominent than in scarlet fever, and there is not the finely diffused redness of the neck and chest observed in that disease. Moreover, the rash is already fading from the face and upper part of the body while extending to the limbs, so that it is less intense on the third day. It leaves some itching, or a very fleeting yellowish tinge, but no discoloured mottling of the skin, and desquamation varying in amount with the extent and severity of the eruption. However little illness is felt at the beginning, a rise of temperature may commence with, or just before, the rash. It may reach 102°–103°, or be only 2° F. above the normal. With rest in bed this may fall one degree by the end of the second day, but is evenly maintained as the eruption proceeds, and subsides with it on the third day. Not infrequently, however, there is no rise of temperature at all. In rare cases there may be a relapse during the second week.

The urine is often high-coloured in the early part of the illness; but there is no albuminuria, nor has this ever been known to follow. In some few cases a transient complaint of sore-throat or of fatigue has been made a week before the rash; or epistaxis has occurred. In delicate children bronchitis, broncho-pneumonia or pleuro-pneumonia are sometimes met with as complications, as also are laryngitis, pharyngitis and middle-ear troubles; enlarged glands and tuberculosis have been found as sequelæ in such cases.

DIAGNOSIS.—The rash may very closely resemble that of measles, but it comes out on the first day instead of the fourth; the catarrhal symptoms, if any, are slight; the fever is slight and quite disproportionate to the amount of the rash, and the rash begins to fade within twenty-four hours. The enlargement of the cervical lymphatic glands is characteristic, and is not seen in measles. In scarlet fever the rash is a uniform punctate redness accompanied by definite throat-symptoms, and often preceded by vomiting; the onset is always sudden and often with serious symptoms. By the fourth day there should be the characteristic strawberry tongue, and the gland behind the angle of the jaw is the only one enlarged. The quarantine-period after a child has been exposed to infection before he is allowed to go back to school or mix with other children should be twenty days, provided that disinfection has been carried out at the commencement of the quarantine. *See* INCUBATION.

PATHOLOGY.—No specific bacillus has as yet been identified, but the existence of such an organism cannot be doubted.

PROGNOSIS.—This is invariably good, except in the case of very delicate children or where the disease precedes or follows on one of the other exanthemata.

TREATMENT.—No special treatment is called for; confinement to the house for a week, and perhaps to bed for a day or so, is almost all that is required in rubella. A patient may be regarded as free from infection in not less than ten days from the appearance of the eruption.

WILLIAM SQUIRE.

JOHN ABERCROMBIE.

RUBEOLA.—A synonym for measles. *See* MEASLES.

RUPIA (ῥύπος, dirt).—Rupia is a term applied to thick conical crusts formed in layers over ulcers of the skin. The word is now only used to designate a very characteristic syphilitic.

The lesion consists of a superficial syphilitic infiltration of the cutis, accompanied by the exudation of serum, the elevation of the overlying epithelium, and the formation of a more or less perfect bulla. Its contents, at first clear or blood-stained, rapidly become purulent. The epidermis covering the lesion gives way, the contents escape and dry on the surface, forming a crust. In the meantime ulceration continues to spread peripherally beneath the crust, the ulcerated surface discharges and more crust is formed. By degrees, the stratified limpet-, or oyster-shell-like crust, which is the characteristic feature of the lesion, is formed. Its apex may be in the centre or towards the circumference depending on the direction in which the superficial ulcer spreads, and a well-formed crust may be half-an-inch thick, and as much as two inches in diameter. An areola of inflammatory redness of the skin is seen surrounding the crust, and on removing the crust the punched-out ulcer—deeper towards the centre—is easily perceptible.

An eruption of rupia is usually not profuse, and often a few only of the crusts present the typical appearance. Some of the lesions show crusts of ecchymatous character, while in other situations the imperfect bullæ, the ulcers, and the cicatrices of previous lesions may be noted. An eruption of rupia may continue for some months and varies in severity according to the condition of the patient; it may occur at almost any period of an attack of syphilis, after that of primary inoculation, and is perhaps most usually seen in cases of virulent infection in weakly or cachectic persons. The scars remaining from the lesions are at first pink, gradually assuming the characteristic white colour and pliant structure of the superficial syphilitic cicatrix; it may show a margin of surrounding pigmentation.

Treatment consists in the careful use of anti-syphilitic remedies, taking special care to sustain the general nutrition of the patient. The ulcers should be carefully treated by antiseptic remedies, so as to prevent them spreading rapidly, as sometimes happens in severe cases of syphilitic cachexia.

JAMES GALLOWAY.

RUPTURE (*rumpo*, I break).—**SYNON.** : Fr. *Ruptures*; Ger. *Risse*.—In addition to its ordinary meaning, this word is used in a popular sense as a synonym for hernia, which is spoken of as a *rupture*. *See* HERNIA.

ST. MORITZ, Upper Engadine, Switzerland.—A bracing mountain winter and summer climate. Baths; whey- and milk-cure. Altitude, 5620 feet. See CLIMATE, Treatment of Disease by; MINERAL WATERS; and PHTHISIS.

ST. PAUL'S.—A city in Minnesota, on the banks of the Mississippi, 1200 feet above sea-level. Well protected from winds. Climate cold, clear, dry, and calm; winters rather extreme. Mean annual temperature 44° F.; the mean daily range 19° ; rainfall 30 inches. A health-resort for phthical patients. See CLIMATE, Treatment of Disease by.

ST. SAUVEUR, in the French Pyrenees.—Sulphur-waters, slightly thermal. See MINERAL WATERS.

ST. VITUS'S DANCE.—A popular synonym for chorea. See CHOREA.

SALAAM-CONVULSIONS.—A form of convulsive-tic characterised by violent bowing movements. See ECSTASY.

SALINE SOLUTION, Infusion of.—DEFINITION.—The introduction into the vessels, either directly or indirectly, of a solution of chloride of sodium (6 per cent.) in water.

Wooldridge was the first to demonstrate that only one of the indications formerly regarded as of importance in transfusion was really essential, viz. the increase of the quantity of circulating fluid. In the severest cases of hæmorrhage there is always enough hæmoglobin left to sustain life, if only there is enough fluid in the vessels to enable the heart to ensure its circulation. Arbuthnot Lane, in 1891, successfully infused $3\frac{1}{2}$ pints of saline into the veins of a girl of 13, suffering from extreme collapse due to hæmorrhage after an operation for cleft palate. The method is now frequently employed and is of great value.

Landerer has proposed the addition of 3 to 5 per cent. of sugar, to render the fluid nutrient, to excite osmosis of the tissue-fluids into the vessels, and better to preserve the red corpuscles. Half an ounce of brandy or ten minims of Liq. Strychninæ is sometimes added with apparent advantage.

INDICATIONS.—1. Dangerous loss of blood from injury or disease. 2. Dangerous collapse from injury or disease. 3. Diabetic coma. 4. Acute delirious insanity with typhoid symptoms. In the first case there is not enough fluid in the vessels; in the second the vascular system, especially the great abdominal veins, is dilated, so that, relatively to the enlarged system, there is too little blood. In diabetic coma the dilution of the blood, and therefore of the poison, has not infrequently been followed by temporary return of consciousness, very rarely by recovery. Only a small number of cases of the fourth group have been published, but in some of these subsidence of symptoms followed the infusion.

METHODS.—1. Intravenous. 2. Subcutaneous. 3. Intra-peritoneal. 4. Rectal.

1. Intravenous Infusion.—The fluid is prepared in a jug or beaked measure by diluting a strong sterile solution of salt, or salt and sugar, with boiled water, so that there shall be one drachm of salt to each pint of water; but, in haste, table-salt may be used and hot water from the tap,

diluted, if necessary, with cold tap-water to bring it to a temperature of 98° – 100° . The writer has never seen harm arise from fluid so prepared. Meanwhile a vein is exposed, usually the largest in the region of the elbow; sometimes the internal saphenous near the ankle, or even the external jugular. The selected vein is cleared from its surroundings for three-quarters of an inch. A fine silk loop is passed behind it with forceps or aneurysm-needle and divided—one half being drawn to the proximal and the other to the distal angle of the wound. The latter thread is tied. A short distance above the knot, a bit of the front of the vein is seized with forceps, and a pointed flap—base upwards—is cut with scissors. The flap is raised by the forceps holding its point, and beneath it a boiled glass or metal nozzle is easily passed into the vein towards the heart. The first hitch of a reef-knot is now tied upon the vein and contained nozzle with the proximal thread.

Before being introduced into the vein, the nozzle should be connected by some four feet of boiled rubber-tubing with the sterilised barrel of a 4-ounce glass-syringe (failing this, with a glass or metal funnel). The saline fluid is poured into the barrel of the syringe and, the tube and nozzle being allowed to hang vertically, all air is expelled, and the apparatus is filled with saline-solution; a clip, close to the nozzle, is then allowed to close upon the tube.

The nozzle being in the vein, the syringe is held well up, and the clip removed; as the fluid runs into the vein, more is poured into the syringe, which should never be allowed to become empty. Two to six pints have been introduced; two to four form the usual quantity. As the nozzle is withdrawn, the hitch upon the silk ligature is tightened upon the vein and the reef-knot is completed. The skin-wound is closed by one or two stitches and a dressing of gauze and collodion.

DIFFICULTIES.—1. *Finding the Vein.*—Even in thin people, the superficial veins may hardly be visible. A ligature round the limb above the point at which it is desired to open the vein may be tried, and the limb should be allowed to hang down. If a suitable vein does not show quickly a short incision should be made at a likely place and the vein exposed.

2. *The Introduction of the Fluid.*—Should any difficulty be experienced in introducing the fluid, see that the vein-wall is not tightly pressed against the oblique opening of the nozzle, and that there is nothing compressing the vein between the nozzle and the heart. Hold the barrel of the syringe as high above the nozzle as possible and raise the limb somewhat; or insert the piston of the syringe and inject. Finally try another vein. The writer has failed with all these expedients—a fore-arm vein and the internal saphenous having been opened, the cause of the difficulty was not discovered. In such a case the external jugular should be tried, but ordinarily, a scar in the neck should be avoided.

Effects.—As the infusion is continued the pulse first becomes palpable at the wrist, and then falls in frequency as it increases in volume. The breathing improves, and the extreme pallor disappears. The infusion should be stopped when a satisfactory improvement has been effected, or when it is obvious that a good result cannot be obtained. It is said that hæmatin from destruction of red corpuscles, has sometimes been found in the urine a day or two

fter saline infusion ; and sometimes a rise of temperature has been attributed to it. Saline infusion has been repeated two to six times in cases of hemorrhage, with ultimate success.

2. Subcutaneous Infusion.—This method is easily carried out by inserting an aspirator-needle deeply into the subcutaneous tissue where this is plentiful and loose. The needle is connected by rubber tubing with a douche-can, raised 5 or 6 feet above the puncture. Howard Kelly prefers this method to the intravenous, though his objections to the latter seem to be chiefly theoretical. In bad cases he runs a needle behind each breast, and in twenty minutes he can thus introduce 700 to 1000 c.c. He has never seen any unpleasant effects. See p. 706.

3. Intraperitoneal Infusion.—In bad abdominal cases many surgeons are in the habit of giving 2 or 3 pints of warm saline solution in the peritoneal cavity, whence it is rapidly absorbed.

4. Rectal Infusion.—Half a pint or a pint of saline solution thrown into the rectum is often very useful in cases of moderate shock. It is rapidly absorbed, and half a pint more may be given in one or two hours. For this purpose the writer frequently substitutes saline beef-tea or peptonised milk-gruel for normal saline ; and to these brandy may be added. These large injections are usually retained, unless there is much vomiting. The anus should be supported by a pad of cotton-wool and by the pressure of the hand during straining ; and the foot of the bed should be well raised.

STANLEY BOYD.

SALINS-MONTIER, in Savoy.—Muriated saline waters, with some iron, iodine, and arsenic. See MINERAL WATERS.

SALISBURY TREATMENT.—A name applied to a form of treatment for obesity, consisting in the limitation of the ingesta to animal food and hot water. See OBESITY.

SALIVARY CALCULUS.—See CONCRETIONS ; and MOUTH, Diseases of.

SALIVARY FISTULA.—See MOUTH, Diseases of.

SALIVARY GLANDS, Diseases of.—SYNON. : Fr. *Maladies des Glandes Salivaires* ; Ger. *Krankheiten der Speicheldrüsen*.

The salivary glands are six in number, distributed in three pairs, viz. the parotid, the sub-maxillary, and the sublingual. These glands and their ducts are liable to inflammation. Obstruction of the ducts, salivary calculus, ranula, and salivary fistula are described in the article MOUTH, Diseases of. All the glands are liable to a specific infective disease known as Cynanche parotidea or Mumps (see MUMPS). The parotid gland is also subject to Simple Parotitis and to Acute or Suppurative Parotitis.

Simple Parotitis.—SYNON. : Inflammation of the Salivary Glands ; Sialodochitis fibrinosa ; Fr. *Grenouillette aiguë*.—In all cases the inflammation enters from the mouth, where the causative factors are to be looked for. These may be obstruction of the mouth of the duct by a foreign body, by swelling

of the epithelium, or by some growth on the buccal mucous membrane. Any of the affections of the mouth (see MOUTH, Diseases of) may induce the condition, either by direct spread of inflammation or by the mechanical obstruction set up. In the sublingual gland it is frequently produced by salivary calculus. It is said to result from cold or injury. Simple inflammation may be limited to the ducts, or may extend to the gland.

The SYMPTOMS consist of a certain amount of constitutional reaction together with pain and swelling in the region of the parotid gland. This latter is found to be uniformly enlarged and elastic. In many cases there is no pain or discomfort further than the mechanical inconvenience ; occasionally there may be both pain and tenderness, though never very acute. The condition and appearances are variable, frequently becoming more marked after meals and decreasing at times.

The TREATMENT consists of attention to the causal conditions, and should chiefly be directed to maintaining the patency of the duct.

Acute Parotitis.—SYNON. : Suppurative Parotitis ; Symptomatic Parotitis ; Metastatic Parotitis.—The term Metastatic Parotitis is an unfortunate one as the condition is in no sense a metastasis, but is a complication arising in several different conditions. It is met with in various fevers—scarlet, enteric, rheumatic, and typhus. It also occurs with pyæmia, pneumonia, and phthisis. Occasionally it has been ascribed to gout. An interesting form is that which follows injuries or diseases of the abdominal or pelvic viscera, and is met with in gastric ulcer, peritonitis, dysentery, intestinal obstruction, and after ovariectomy and catheterisation.

Suppurative Parotitis may spread from the mouth along Stensen's duct, when suppuration occurs primarily within the tubules. When it occurs in the course of pyæmia or as a sequela of one of the exanthemata the pus may form in the interstitial tissue. Several glands may be affected simultaneously, but the inflammation is generally limited to the parotid and to one side. The gland becomes enlarged ; the skin over it is shiny, tense, and exceedingly painful. This is chiefly due to the firm fascia covering the gland. This is bound over it so firmly that the suppuration, which is so apt to ensue, cannot readily find its way to the surface, and may discharge into the external auditory meatus or the mouth, or burrow among the muscles of the neck, or even pass upwards and inwards towards the base of the skull. Under these circumstances the constitutional symptoms from septic absorption are generally severe. When it occurs in the course of an acute disease the subjective symptoms may not be so marked and the course of the complication is sometimes less evident. Probably the first indication of the parotitis is a little swelling about the lobe of the ear and some loss of the usual depression between the ramus of the lower jaw and the mastoid process, and its replacement by a more or less hard tumour. Pressure on this will elicit an expression of pain.

The inflammation may end in either resolution or suppuration. The former termination may be looked for if the swelling has formed slowly and during the convalescence from acute disease. When suppuration takes place it is revealed by the irregularly reddened appearance of the swelling, the detection of fluctuation, and the severity of the symptoms. Pyæmic symptoms are apt to supervene

owing to the retention and deep spread of pus, as well as to the fact that large veins and arteries pass through the parotid gland.

PATHOLOGY.—*Post-mortem* examinations show that the duct is always affected and that the lobules of the gland are more or less destroyed before the interstitial tissue is attacked. In this stage the gland appears as if studded with small suppurating islands. At a later period not only does the phlegmonous inflammation reach the interstitial tissue, but spreads to the neighbouring connective tissue enveloping the muscles, by which it is directed downwards even as low as the clavicle, or up to the base of the brain.

The pathogeny of the affection has been much discussed, but still remains uncertain. That it is due to microbic invasion is certain, but nothing has been settled as to the actual organism concerned nor as to how it gains access to the gland. There can be little doubt that its route is along the duct, and that the diminished resistance of the patient is a powerful contributing factor.

DIAGNOSIS.—Some lymphatic glands lie on the outer side of the parotid, and are not infrequently inflamed. This condition can be distinguished from parotitis by observing that these glands are superficial, and that the *socia parotidis* is not enlarged.

PROGNOSIS.—If this disease develops slowly and during convalescence the prognosis is favourable. On the other hand, its occurrence is of the gravest importance if it appears during the acute period of the primary disease. Trousseau remarks that it is an affection from which he has rarely seen enteric or other patients recover.

TREATMENT.—The treatment should be both prophylactic and symptomatic. In all cases of acute disease of an adynamic type particular attention must be given to the care and cleanliness of the teeth and mouth. When there is any suspicion of the parotid gland being affected, attention should be directed to the patency of Stensen's duct, along which, if necessary, a fine probe can be passed, while its orifice is well cleansed with warm alkaline lotions. In the early stages warm fomentations and poultices should be applied, and the pain may to some extent be relieved by the local use of belladonna. The patient's general condition will require increased care, particularly with regard to nourishment, stimulants, and tonics. As soon as pus has formed it should be evacuated. In doing this care must be taken to avoid injury to the facial nerve, and Hilton's method of operating may be advantageously employed.

Tumours of the Parotid Gland.—These may be (a) simple, or (b) malignant. A chronic enlargement may remain for some time after an attack of Mumps or inflammatory Parotitis.

The simple parotid tumours frequently originate in the superficial parts of the gland. They vary much in structure, and among those met with are cysts, fibromata, lipomata, angiofibromata, angio-lymphomata, and tumours of a mixed type. Cartilaginous elements are sometimes met with in these growths, probably due to the persistence of remnants of the embryonic Meckel's cartilage.

Malignant tumours of the parotid occur in the form of either sarcoma or epithelioma. A correct and early diagnosis is of importance, and as the treatment for both classes of tumour can only be operative, a work on surgery must be consulted.

ST. CLAIR THOMSON.

SALIVATION (*Salivatio*; *σάλισμός*).—**SYNON.** : Ptyalism; Fr. *Salivation*; Ger. *Speichelfluss*.—The term is given to an extraordinarily profuse flow of saliva, which is apt to occur under many various conditions. Ptyalism is therefore a symptom and cannot be regarded as a distinct affection, but it obtains a position as an independent disorder in the nomenclature of disease, and therefore requires a separate notice.

ÆTIOLOGY.—The causes of salivation are numerous. Mental conditions will sometimes produce an increased and persistent flow, just as fear will arrest the secretion. Any direct irritation of the mouth is apt to be associated with increased flow of saliva, and hence it is met with in dentition, aphtha, thrush, the various forms of ulceration, cancrum oris, glossitis, &c. It may be set up by reflex irritation in neuralgia and gastric affections, and is sometimes one of the most persistent complications of pregnancy. It is also said to be produced by irritating causes in the liver, spleen, and genital organs. It is met with in hydrophobia and small-pox. The free dribbling of saliva is a striking symptom of bulbar paralysis, but it is not settled whether there is in this disease actual increase of secretion or merely an escape of it through the open lips. This dribbling of saliva—which should be distinguished from salivation—is also met with in double facial paralysis, tonsillitis, mumps, typhus fever, tabes dorsalis, and in the insane. Among the drugs which give rise to ptyalism are iodide of potassium, arsenic, copper, and pilocarpine; but in actual practice all these various ætiological factors are rarely met with in comparison with the frequency with which mercury is found to be the cause. Salivation from mercury is much less frequent than formerly, and is rare in an acute form. There are some subjects with a peculiar idiosyncrasy for this drug, in whom a very small dose—1 gr. of calomel, or even less—will produce decided salivation. But apart from such cases only mild degrees of salivation are met with nowadays.

SYMPTOMS.—The symptoms of salivation are evident enough. The individual complains of the increased secretion in his mouth, interfering possibly with his speaking, swallowing, and even sleeping. When due to mercury the salivation may be preceded by a metallic or 'coppery' taste in the mouth, tenderness of the gums, and a disagreeable odour from the breath. In marked cases this last may be horribly fetid, while the gums become spongy, bleed readily, and recede from the teeth, which are loosened in their sockets. The tongue is large and flabby, the patient is constipated, and emaciation ensues. If the case goes still further there is ulceration of the gums and mouth, and the teeth may fall out. While these symptoms are developing the increase in the secretion of saliva has become so marked that it pours from the patient's mouth night and day. Tired of wiping it away, he may place some receptacle beneath his mouth into which he allows it to dribble during the day; at night he has to protect his pillows by cloths placed below his chin. Instead of the usual 1 to 2 quarts per day, the quantity secreted in twenty-four hours may amount to as much as 5 quarts. The specific gravity generally falls from 1006 to 1002 or 1001. In a well-marked case the condition may persist for two or three weeks.

TREATMENT.—When due to some nervous disorder, the increased secretion of saliva may be

checked by 10-drop doses of tincture of belladonna three times a day, or by the administration of liquor atropinæ $m\frac{1}{4}-\frac{1}{2}$ with liquor strychninæ $mijj-vj$. With careful prophylactic measures salivation from mercury can be avoided in a majority of cases, and need never be severe. Before starting treatment it is well, if possible, to see that the teeth and mouth are rendered as clean and healthy as possible. The dose of mercury should be small at first, and the patient frequently observed until it is seen how he tolerates it. A good precaution is to note his weight frequently and see that it does not decline. Great care should be taken of the mouth and teeth during treatment, and if there is any dental caries it is well to prohibit smoking and spirit-drinking. When any symptoms of salivation appear, the administration of mercury should be discontinued; the mouth should be frequently washed with lotions of chlorate of potassium, alum, myrrh, &c.; and the excretion of the drug from the system may be promoted by giving iodide of potassium, which fortunately generally benefits the condition for which the mercury was being administered. If due to iodide of potassium it is said that the symptoms are relieved by the free administration of bicarbonate of sodium. According to some authorities salivation may be avoided if small doses of chlorate of potassium are administered along with the mercury.

ST. CLAIR THOMSON.

SALSOMAGGIORI, in Italy.—Very rich iodine- and bromine-waters. This resort is at the foot of the Apennines, 520 feet above the sea-level. *See* MINERAL WATERS.

SALTATORY SPASM.—A nervous affection, consisting in alternating contractions of the flexor and extensor muscles of the legs induced by the pressure of the soles of the feet upon the ground, and best marked therefore in the standing posture. Gradual recovery is usual, but the disease is sometimes associated with permanent lesions of the spinal cord.

SALZBRUNN, in German Silesia.—Alkaline waters. *See* MINERAL WATERS.

SALZKAMMERGUT, in Austria.—An inland bracing summer climate. *See* CLIMATE, Treatment of Disease by; and ISCHL.

SALZUNGEN, in Saxe-Meiningen.—Cold muriated saline waters. *See* MINERAL WATERS.

SAN DIEGO.—A health resort in South California, on the Pacific Coast. A dry bracing climate, resembling that of Santa Barbara, free from fog, and equable. Mean temperature 60° F.; the records seldom rise to 80° or sink to the freezing-point. Mean daily range only 15° . Average rainfall 10 inches. Winds principally from the north-west. Well suited for pulmonary complaints. *See* CLIMATE, Treatment of Disease by.

SANDOWN, in the Isle of Wight.—Exposure S.E. Mean temperature 51.4° . An open, bright, bracing health-resort, with good sea-bathing. *See* CLIMATE, Treatment of Disease by; and SEA-AIR and SEA-BATHS.

SAND-WORM.—A term sometimes employed to designate the sand-flea or jigger. *See* CHIGOE.

SANITARY LAW.—The first laws which were passed in England relating to sanitary matters were directed successively against the scourges plague, small-pox, and cholera, and these were placed under control by various statutes which were passed between 1603 and the commencement of the reign of Victoria.

The statute of 1 Jac. I. c. 31 made it a capital offence for any person having an infectious sore upon him uncured to go abroad and converse in company, after being commanded by the proper authority to keep his house. That Act was repealed in the first year of the last reign (1837), but some statutes relating to quarantine, which were passed in the first instance for the purpose of dealing with plague, remain in force to the present day. Small-pox was not the subject of legislation until a generation after the discovery of vaccination, and the first Act dealing with it was passed in 1840 (*see* VACCINATION). Cholera became the subject of legislation in 1832, after the serious visitation with which the country had then been afflicted. By the law that was then passed the Privy Council were empowered to issue such orders as appeared expedient for the purpose of preventing the spread of the epidemic, for securing the proper burial of the dead, and for relieving the necessities of persons suffering from the malady. Apart from epidemic disease, the Legislature was slow to deal with sanitary precautions, and it was left to private persons to vindicate the public right to have nuisances abated by the enforcement of the common law. This procedure was tedious, costly, and uncertain, and hence, in boroughs and populous towns, special local statutory powers were frequently obtained.

Boards of commissioners for the paving, improvement, lighting, and watching of towns were formed for many places under the sanction of Parliament, and these bodies, together with the reformed municipalities created by the Municipal Corporations Act of 1835, formed the nucleus around which developed the local governing bodies as we know them to-day. The first conception of a local authority was that of a body whose existence, except in the case of a corporation created by charter, could only be brought about by the direct sanction of Parliament given by way of a local Act. This procedure, though at first cumbersome, was, under the Ministry of Sir Robert Peel, greatly simplified by the passing of what have been long known as the Model Clauses Acts. The effect of this improvement was to enable comparatively short local Acts to be passed, and to incorporate by mere reference a large number of useful provisions relating to various matters of sanitary and other local administration. Owing, however, to the costliness of obtaining parliamentary sanction to local bills, there was a growing demand for some simpler method of creating a local governing body in a town of sufficient importance to require one; and the sanitary commissioners who had been examining the condition of the country having reported as to the great need for the establishment of a general scheme of local government for towns and populous districts, the attention of Parliament was at length seriously directed to the matter. After two unsuccessful attempts the Public Health Act of 1848 was passed. By this epoch-marking statute a general board of health was established and power was given to it to cause the Act to be applied to any place having a known and defined boundary. These

provisions were taken advantage of freely, and the regulation of such matters as the laying out and sewerage of streets, the construction and drainage of houses, the provision of a water-supply to towns, and the removal of nuisances, were put within the easy reach of towns that had previously been subject to no control whatever. Ten years later this Act was amended and replaced by the Local Government Act, 1858, which Act remained in force till 1875, and under it about eight hundred local boards were formed up to 1872. As a result of the report of the Sanitary Commission of 1869, the scheme of local government was carried still further by the passing of the Public Health Act, 1872, under which the whole country was divided into urban and rural sanitary districts, and the Sanitary Acts applied to the entire country. And when the Public Health Act, 1875, which repealed and consolidated all the previous statutes outside the metropolis that related to sanitary law, was passed, this arrangement was not disturbed, and it now forms the basis of local government as settled by the Local Government Act, 1894. In 1901 there were in existence 1,150 urban authorities and 676 rural authorities, and under the Act mentioned these bodies are continued in force, under the description of urban district councils and rural district councils, for urban districts and rural districts respectively. Of the urban districts, 64 were county boroughs, 244 were non-county boroughs, and the rest were urban districts.

In addition to these bodies, every rural parish having a population of three hundred or upwards has a parish council; and such rural parishes as have a population of one hundred or upwards are enabled to have a parish council if they so resolve, and provision is made to form or dissolve a parish council if the population changes. Some parishes may by order of the county council be grouped under a common parish council. In addition to these bodies, there is in rural districts the parish meeting for every 'rural parish' in such district. This consists of the persons known as the parochial electors—that is, the persons who are registered on the parliamentary and local government register of electors—for the parish. Taking them in order of importance, there are the following local governing bodies: (1) Councils for counties; (2) Councils for municipal boroughs; (3) Councils for urban districts which are not boroughs; and (4) Councils for rural districts. For the purposes of sanitary administration the urban and rural district councils are the most important bodies, and the jurisdiction of the county councils over them is very limited. In some cases, such as the provision of sewerage and water-supply, a parish council has the right to complain to the county council that the rural district council is in default, and the county council can thereupon supersede that body. In the case of urban district councils in default an appeal lies to the Local Government Board.

It is unnecessary here to set forth the mode of election and qualifications of councillors or the details of the constitution of the councils; but it may be stated in general terms that the councils consist of members who are called councillors, and who are elected by the registered electors, with the addition, in the case of municipal corporations and county councils, of aldermen who are elected by the councillors. The constitution of county councils is determined by the Local Government Act, 1888; of

municipal corporations by the Municipal Corporations Act, 1882; and of urban and rural district councils by the Local Government Act, 1894.

It will now be necessary to describe in detail the powers of the local authorities, and the rights and liabilities of individuals in England and Wales, with special reference to sanitary matters only.

POWERS OF LOCAL AUTHORITIES.—A. County Councils.—By the Local Government Act, 1888 (section 17), it is provided that a county council may appoint one or more medical officers of health, and may make arrangements for rendering the services of any such officer regularly available in the district of any district council; and section 19 further provides that if it appears to a county council from the report of the medical officer of health of any district that the Public Health Act, 1875, has not been properly put in force within the district to which the report relates, or that any other matter affecting the public health of the district requires to be remedied, the council may cause a representation to be made to the Local Government Board on the matter. Such a representation would enable that Board to put in force the powers conferred upon them by section 299 of the Public Health Act, 1875. Under that section they may issue an order limiting the time for the local authority to perform its duty; and if such duty is not performed by the time so limited, the order may be enforced by writ of *mandamus*, or the Board may appoint some person to perform such duty.

B. Urban and Rural District Councils.—It is declared by section 7 of the Housing of the Working Classes Act, 1885, to be the duty of every local authority entrusted with the execution of laws relating to public health and local government to put in force from time to time, as occasion may arise, the powers with which they are invested, so as to secure the proper sanitary condition of all premises. These and other powers possessed by urban authorities under the sanitary laws will now be explained. They may be roughly divided into powers (1) which relate to the improvement of the general sanitary condition of the district viewed in its physical aspects; (2) which relate to the maintenance of dwellings and their surroundings, as well as factories and workshops, in a proper sanitary condition. It must be borne in mind that the powers here described are those exercisable by urban authorities, and that the powers of rural authorities, though capable of being extended, as occasion arises, by means of orders issued by the Local Government Board, are under the Public Health Acts limited to certain matters only.

1. *Powers which relate to the improvement of the general sanitary condition of the district.*

Sewerage.—Foremost under this heading comes the provision of sewers, and these the local authority is required to make so far as may be necessary for effectually draining their district. Thus the surface-water and the sewage will be carried off, but it must not be discharged into any stream until it has been purified. Sewage may be disposed of or dealt with by any suitable method, and sewage-works can be provided for the purpose, either in or out of the district of the local authority. One local authority may agree for the communication of their sewers with those of another in an adjoining district.

Water-Supply.—A local authority may provide their district or any part of it with a supply of water proper and sufficient for public and private purposes, and may (1) construct and maintain waterworks, dig wells, and do any other necessary acts; (2) take on lease or hire any waterworks, and (with the sanction of the Local Government Board) purchase any waterworks, or any water or any right to take or convey water, either within or without their district, and any rights, powers, and privileges of any water-company; and (3) contract with any person for a supply of water.

Before commencing to construct waterworks within the limits of supply of any water-company empowered by Act of Parliament or any order confirmed by Parliament to supply water, the local authority must give written notice to every water-company within whose limits of supply the local authority are desirous of supplying water, stating the purposes for which and (as far as may be practicable) the extent to which water is required by the local authority.

It is not lawful for the local authority to construct any waterworks within such limits if and so long as any such company are able and willing to supply water proper and sufficient for all reasonable purposes for which it is required by the local authority; and any difference as to whether the water which any such company are able and willing to lay on is proper and sufficient for the purposes for which it is required, or whether the purposes for which it is required are reasonable, or as to the charges, must be settled by arbitration.

The provisions of the Waterworks Clauses Acts with regard to communication-pipes, the waste or misuse of water, the fouling of water, and the payment and recovery of water-rates, are incorporated with the Public Health Act, 1875, and in this way local authorities are enabled to take advantage of the powers which are generally conferred on water-companies for carrying out the supply of water to any district.

Pollution of Rivers.—Any local authority, with the sanction of the Attorney-General, may, either in their own name or in the name of any other person, with the consent of such person, take proceedings under the Public Health Act for the purpose of protecting any watercourse within their jurisdiction from pollutions arising from sewage either within or without their district. Besides these powers, the Rivers Pollution Prevention Acts require local authorities to enforce a number of penal provisions which are designed to prevent the fouling of streams by solid matters, by sewage, or by manufacturing or mining refuse.

Polluted Wells.—Under the Public Health Act, 1875, it is provided that, on the representation of any person to any local authority that within their district the water in any well, tank, or cistern, public or private, or supplied from any public pump, and used or likely to be used by man for drinking or domestic purposes, or for manufacturing drinks for the use of man, is so polluted as to be injurious to health, such authority may apply to a court of summary jurisdiction for an order to remedy the same; and thereupon such court shall summon the owner or occupier of the premises to which the well, tank, or cistern belongs if it be private, and in the case of a public well, tank, cistern, or pump, any person alleged in the application to be interested in the same, and may either dismiss the

application, or may make an order directing the well, tank, cistern, or pump to be permanently or temporarily closed, or the water to be used for certain purposes only, or such other order as may appear to them to be requisite to prevent injury to the health of persons drinking the water. The court may, if they see fit, cause the water complained of to be analysed at the cost of the local authority applying to them under this section.

Streets.—All streets which are highways repairable at the expense of the inhabitants, and the pavements, stones, and other materials provided for the purposes of the highways by any surveyor of highways, belong to the local authority, and are under their management and control. They must level, pave, flag, channel, alter, and repair the streets as occasion may require, and may raise, lower, or alter the soil, and may place and keep in repair fences and posts for the safety of foot-passengers. They may regulate the line of buildings in streets by reference to existing buildings, but they cannot prescribe a building-line. They may make by-laws as to the width and construction of new streets. The local authority can undertake or contract for the proper cleansing of streets, the removal of house-refuse from premises, and the cleansing of earth-closets, privies, ashpits, and cesspools, and may by public notice require the periodical removal of manure or other refuse-matter from stables or other premises.

Cemeteries.—Under the Public Health (Interments) Act, 1879, a local authority may provide a cemetery, and the provisions of the Cemeteries Clauses Act, 1847, are made applicable. Where the Burial Acts are in force, burial grounds may be provided by the local authorities who exercise the functions of a burial board, or by a specially appointed burial board itself. The control of burial boards was formerly vested in the Home Secretary, but it has now been transferred to the Local Government Board under the Burials Act, 1900.

Pleasure-Grounds.—An important power, the exercise of which must have a very important bearing on the general well-being of our towns, is that which enables a local authority to provide pleasure-grounds for its district. A local authority can provide and maintain public walks and pleasure-grounds and other open spaces by the exercise of the powers conferred by the Public Health Acts and the Open Spaces Acts.

2. *Powers which relate to the maintenance of dwellings and their surroundings, as well as factories and workshops, in a proper sanitary condition.*

Construction of Buildings.—The Public Health Acts contain many important provisions relating to the sanitary condition of dwelling-houses, but the most important are those which authorise the making of by-laws for regulating the erection of new buildings, as defects may be prevented at the outset that could not be remedied at a later stage. This power of making by-laws enables the local authority to require plans of every new building; to regulate the thickness of walls, and the provision of damp-proof courses; to require the site under the floors to be covered with concrete; to regulate the height of rooms; to prescribe definite areas of open space in front and rear so as to secure a free circulation of air; to require that drains shall be properly laid and ventilated; to regulate the mode of construction of water-closets,

privies, ashpits, and cesspools, and their distance from dwellings and sources of water-supply, as well as many other matters. The powers are contained in section 157 of the Act of 1875, as amended by section 23 of the Act of 1890, which latter Act is only in force in the districts which adopt it. These sections are as follows: The Public Health Act, 1875, section 157, provides, as regards buildings, that every urban authority may make by-laws with respect to the following matters—that is to say: With respect to the structure of walls, foundations, roofs, and chimneys of new buildings, for securing stability and the prevention of fires, and for purposes of health; With respect to the sufficiency of the space about buildings, to secure a free circulation of air, and with respect to the ventilation of buildings; With respect to the drainage of buildings, to water-closets, earth-closets, privies, ashpits, and cesspools in connection with buildings, and to the closing of buildings or parts of buildings unfit for human habitation, and to prohibition of their use for such habitation.

And the Public Health Acts (Amendment) Act, 1890, section 23, provides that the above-cited section shall be extended so as to empower every urban authority to make by-laws with respect to the following matters—that is to say: The keeping water-closets supplied with sufficient water for flushing; the structure of floors, hearths, and staircases, and the height of rooms intended to be used for human habitation; and the paving of yards and open spaces in connection with dwelling-houses.

By section 23 of the Act of 1890, it is further provided as follows: 'Every local authority may make by-laws to prevent buildings which have been erected in accordance with by-laws made under the Public Health Acts from being altered in such a way that if at first so constructed they would have contravened the by-laws.' All by-laws made under these enactments require to be confirmed by the Local Government Board, but before such confirmation can be obtained notice of intention to apply for confirmation must be given, in one or more of the local newspapers circulated within the district to which the by-laws relate, one month at least before the making of the application; and for one month at least before the application, a copy of the proposed by-laws must be kept at the office of the sanitary authority, and must be open during office hours thereat for the inspection of the ratepayers of the district to which the by-laws relate, without fee or reward. When such by-laws have been made, it is the duty of the local authority to enforce them against every one with impartiality. The Local Government Board have issued separate model codes of by-laws for urban and rural districts.

Drainage.—It is not lawful in any urban district newly to erect any house or to rebuild any house which has been pulled down to or below the ground floor, or to occupy any house so newly erected or rebuilt, unless and until a covered drain or drains be constructed, of such size and materials, and at such level, and with such fall as, on the report of the surveyor, may appear to the urban authority to be necessary for the effectual drainage of such house; and the drain or drains so to be constructed must empty into a sewer which the urban authority are entitled to use, and which is within one hundred feet of some part of the site of the house to be built or rebuilt; but if no such means

of drainage are within that distance, then into such covered cesspool or other place, not being under any house, as the urban authority direct.

Cleansing.—Where, on the certificate of the medical officer of health or of any two medical practitioners, it appears to any local authority that any house or part thereof is in such a filthy or unwholesome condition that the health of any person is affected or endangered thereby, or that the whitewashing, cleansing, or purifying of any house or part thereof would tend to prevent or check infectious disease, the local authority are required to give notice in writing to the owner or occupier of such house or part thereof to whitewash, cleanse, or purify the same, as the case may require.

Water-Supply.—Where, on the report of the surveyor of a local authority, it appears to such authority that any house within their district is without a proper supply of water, and that such a supply of water can be furnished thereto at a cost not exceeding the water-rate authorised by any local Act in force within the district, or where there is not any local Act so in force, at a cost not exceeding twopence a week, or at such other cost as the Local Government Board may, on the application of the local authority, determine under all the circumstances of the case to be reasonable, the local authority may give notice in writing to the owner, requiring him, within a time therein specified, to obtain such supply, and to do all such works as may be necessary for that purpose. If such notice is not complied with within the time specified, the local authority may, if they think fit, do such works and obtain such supply, and for that purpose may enter into any contract with any water-company supplying water within their district; and water-rates may be made and levied on the premises by the authority or company which furnishes the supply, and may be recovered as if the owner or occupier of the premises had demanded a supply of water and were willing to pay water-rates for the same.

Particular Classes of Dwellings.—In regard to particular classes of dwellings, there are special provisions in the Public Health Acts. Such provisions relate to cellar-dwellings, common lodging-houses, and houses let in lodgings or occupied by members of more than one family. As to the first, it is provided that it shall not be lawful to let or occupy or suffer to be occupied separately as a dwelling any cellar (including for the purposes of the Act in that expression any vault or underground room) built for rebuilt after the passing of the Act (viz. August 11, 1875), or which was not lawfully so let or occupied at the time of the passing of the Act. But cellar-dwellings which were then in actual occupation are allowed to be used subject to certain limitations as to height and situation.

A person may not keep a common lodging-house or receive a lodger therein unless the house is registered in accordance with the provisions of the Act, nor unless his name as the keeper thereof is entered in the register kept under the Act; but when the person so registered dies, his widow or any member of his family may keep the house as a common lodging-house for not more than four weeks after his death without being registered as the keeper thereof.

A house may not be registered as a common lodging-house until it has been inspected and ap-

proved for the purpose by some officer of the local authority; and the local authority may refuse to register as the keeper of a common lodging-house a person who does not produce to the local authority a certificate of character, in such form as the local authority direct, signed by three inhabitant householders of the parish, respectively rated to the relief of the poor of the parish within which the lodging-house is situate for property of the yearly rateable value of six pounds or upwards.

The most effective control that can be exercised over common lodging-houses is that obtained by means of by-laws which every local authority is required to make: (1) for fixing and from time to time varying the number of lodgers who may be received into a common lodging-house, and for the separation of the sexes therein; and (2) for promoting cleanliness and ventilation in such houses; and (3) for the giving of notices and the taking precautions in the case of any infectious disease; and (4) generally for the well ordering of such houses.

As regards houses let in lodgings which are not common lodging-houses, but are commonly known as lodging-houses or tenement-houses, the only special control that can be exercised is by means of by-laws under section 90 of the Public Health Act, 1875. This section is put in force in the district of every local authority by section 8 of the Housing of the Working Classes Act, 1885, and its provisions are very much the same as those of the section relating to by-laws for common lodging-houses.

Conditions to be Implied on Letting Houses for the Working Classes.—It is provided by section 12 of the Housing of the Working Classes Act, 1885, that in any contract for letting for habitation by persons of the working classes a house or part of a house, there shall be implied a condition that the house is at the commencement of the holding in all respects reasonably fit for human habitation. The expression 'letting for habitation by persons of the working classes' means the letting for habitation of a house or part of a house at a rent not exceeding in England the sum named as the limit for the composition of rates by section 3 of the Poor Rate Assessment and Collection Act, 1869.

Nuisances.—Coming now to general nuisances, we find that section 91 of the Public Health Act, 1875, as amended by section 9 of the Housing of the Working Classes Act, 1885, and by the Factory and Workshops Acts, 1878 to 1901, sets out a comprehensive list of nuisances which are capable of being abated, and for the abatement of which the local authority is empowered to serve notices, and on the non-compliance with the terms thereof to apply to a court of summary jurisdiction for an order requiring the abatement of the nuisance, or prohibiting its recurrence, and directing the execution of any works necessary to secure that end. The nuisances which are liable to be dealt with in this way are set out as follows:—

(1) Any premises (including a tent, van, shed, or similar structure used for human habitation) in such a state as to be a nuisance or injurious to health.

(2) Any pool, ditch, gutter, watercourse, privy, urinal, cesspool, drain, or ashpit, so foul or in such a state as to be a nuisance or injurious to health.

(3) Any animal so kept as to be a nuisance or injurious to health.

(4) Any accumulation or deposit which is a nuisance or injurious to health.

(5) Any house or part of a house or a tent, van, shed, or similar structure used for human habitation, so overcrowded as to be dangerous or injurious to the health of the inmates, whether or not members of the same family.

(6) Any factory, workshop, or workplace not kept in a cleanly state, or not ventilated in such a manner as to render harmless as far as practicable any gases, vapours, dust, or other impurities generated in the course of the work carried on therein that are a nuisance or injurious to health, or so overcrowded while work is carried on as to be dangerous or injurious to the health of those employed therein.

(7) Any fireplace or furnace which does not as far as practicable consume the smoke arising from the combustible used therein, and which is used for working engines by steam, or in any mill, factory, dyehouse, brewery, bakehouse, or gaswork, or in any manufacturing or trade process whatsoever; and

Any chimney (not being the chimney of a private dwelling-house) sending forth black smoke in such quantity as to be a nuisance.

Since the Factory and Workshops Act, 1891, the duty of enforcing the sanitary provisions of the law in the case of all factories and workshops is vested in local authorities, and the powers are extended under the Factory and Workshops Act, 1901.

The local authority, or any of their officers, must be admitted into any premises for the purpose of examining as to the existence of any nuisance thereon, or of enforcing the provisions of any Act in force within the district requiring fireplaces and furnaces to consume their own smoke, at any time between the hours of nine in the forenoon and six in the afternoon; or in the case of a nuisance arising in respect of any business, then at any hour when such business is in progress or is usually carried on. In the case of tents, vans, sheds, and similar structures, entry can only be demanded between six o'clock in the morning and the succeeding nine o'clock in the evening.

Where under the Act a nuisance has been ascertained to exist, or an order of abatement or prohibition has been made, the local authority or any of their officers must be admitted from time to time into the premises between the hours aforesaid until the nuisance is abated, or the works ordered to be done are completed, as the case may be.

If admission to premises for any of these purposes is refused, any justice on complaint thereof on oath by any officer of the local authority may, by order under his hand, require the person having custody of the premises to admit the local authority, or their officer, into the premises during the hours aforesaid, and if no person having custody of the premises can be found, the justice shall, on oath made before him of that fact, by order under his hand, authorise the local authority, or any of their officers, to enter such premises during the hours aforesaid.

Any order made by a justice for admission of the local authority, or any of their officers, on premises will continue in force until the nuisance has been abated, or the work for which the entry was necessary has been done.

Where an order of abatement or prohibition has not been complied with, or has been infringed, the

local authority, or any of their officers, are entitled to be admitted from time to time at all reasonable hours, or at all hours during which business is in progress or is usually carried on, into the premises where the nuisance exists, in order to abate the same.

It is the duty of every local authority to cause to be made from time to time an inspection of their district, with a view to ascertain what nuisances exist calling for abatement under the powers of the Public Health Act, and to enforce the provisions of the Act in order to abate the same; also to enforce the provisions of any Act in force within their district requiring fireplaces and furnaces to consume their own smoke.

In addition to the above offences, which are described in the Public Health Act, 1875, as nuisances in every district, whether urban or rural, there is a section (s. 47) which is specially applicable to urban districts. It provides that every person who in an urban district (1) keeps any swine or pigsty in any dwelling-house, or so as to be a nuisance to any person; or (2) suffers any waste or stagnant water to remain in any cellar or place within any dwelling-house for twenty-four hours after written notice to him from the urban authority to remove the same; or (3) allows the contents of any water-closet, privy, or cesspool to overflow or soak therefrom, shall for every such offence be liable to a penalty; and the local authority must abate the nuisance in the manner indicated above.

Every urban authority has power to make by-laws for the prevention of nuisances arising from snow, filth, dust, ashes, and rubbish, and the prevention of the keeping of animals on any premises so as to be injurious to health. Under these powers the deposit and removal of accumulations of filth may be controlled, and the keeping of swine and other animals placed under restrictions. These powers are further extended where the Public Health Acts (Amendment) Act, 1890, is in force, for that enactment confers on local authorities power to make by-laws for prescribing the times for the removal or carriage through the streets of any faecal or offensive or noxious matter or liquid, whether it is in course of removal, or carriage from within or without, or through the district; and requiring that the vessel, receptacle, cart, or carriage used for this purpose is properly constructed and covered so as to prevent the escape of any of the contents, and for compelling the cleansing of any place on which any such matter or liquid has been dropped or spilt in the removal or carriage. The model by-laws of the Local Government Board on this subject may usefully be consulted.

Offensive Trades.—Offensive trades are at times a source of great nuisance, and this was recognised by the framers of the Public Health Act, 1848, the provisions of which Act have been substantially incorporated in the Act of 1875. It is there enacted that any person who establishes any of the offensive trades specified (which are the trades of blood-, bone-, soap-, and tripe-boiler, fell-monger, and tallow-melter), or 'any other noxious or offensive trade, business, or manufacture,' without the consent in writing of the urban authority, shall be liable to penalties. The defect of the earlier Act was that proceedings with respect to offensive trades could only be taken within the limits of a city, town, or populous district; and it was necessary to show that the person complained

of was not using the best practicable means to abate the nuisance. Under the Act of 1875 the proceedings in question may be taken by the authority in any urban district, and the burden of proof that the best practicable means are used to abate the nuisance is thrown upon the defendant. Any urban authority may from time to time make by-laws with respect to any offensive trades established with their consent, in order to prevent or diminish the noxious or injurious effects thereof. It may be well to point out that any 'other' trade besides those specified in the Act to be within the powers of the Act must be *ejusdem generis*. Hence it has been held that brick-burning and the keeping of a fried-fish shop are not 'offensive trades,' but that the business of a rag-and-bone merchant is an offensive trade within the terms of the Act.

Slaughter-houses.—Closely allied to offensive trades are slaughter-houses, and as to these the powers of the Public Health Acts are very extensive. In the first place, every slaughter-house in existence before the Local Government Acts were in force in the place where it is situated has to be registered, and all new ones have to be licensed. Under the Public Health Acts (Amendment) Act, 1890, the license may be made an annual one. The local authority may make by-laws dealing among other things with the maintenance of the slaughter-houses in a cleanly and proper state, and requiring a sufficient supply of water to be provided.

Hospitals.—Of late years great progress has been made in dealing with infectious disease by the provision, under the powers of the Public Health Act, 1875, and the Isolation Hospitals Acts, 1893 and 1901, of hospitals to which patients can be removed. Any local authority may provide for the use of the inhabitants of their district hospitals or temporary places for the reception of the sick, and for that purpose may themselves build such hospitals or places of reception; or contract for the use of any such hospital or part of a hospital or place of reception; or enter into any agreement with any person having the management of any hospital, for the reception of the sick inhabitants of their district, on payment of such annual or other sum as may be agreed on; and two or more local authorities may combine in providing a common hospital.

Where any suitable hospital or place for the reception of the sick is provided within the district of a local authority, or within a convenient distance of such district, any person who is suffering from any dangerous infectious disorder, and is without proper lodging or accommodation, or lodged in a room occupied by more than one family, or is on board any ship or vessel, may, on a certificate signed by a legally qualified medical practitioner, and with the consent of the superintending body of such hospital or place, be removed, by order of any justice, to such hospital or place at the cost of the local authority; and any person so suffering, who is lodged in any common lodging-house, may, with the like consent and on a like certificate, be so removed by order of the local authority; and any person who wilfully disobeys or obstructs the execution of such order will be liable to a penalty not exceeding ten pounds. It is further provided by the Infectious Disease (Prevention) Act, 1890, that any justice of the peace, upon proper cause shown to him, may, where the Act (which is adoptive) is put in operation, make an order directing the detention in hospital, at the cost of the local authority, of any

person suffering from an infectious disease, who is then in a hospital for infectious disease, and would not, on leaving the hospital, be provided with lodging or accommodation in which proper precautions could be taken to prevent his spreading the disorder. The order may be limited to some specific time, but any justice has power to enlarge the time as often as may appear to him to be necessary.

Notification of Infectious Disease.—The Infectious Disease (Notification) Acts, 1889 and 1899, and the Infectious Disease (Prevention) Act, 1890, contain some very important provisions which it is proposed now to describe.

The Infectious Disease (Notification) Act, 1889, was originally adoptive, but by the Infectious Disease Notification Extension Act, 1899, was put in force in every district throughout the kingdom. Under the Act it is provided that where an inmate of any building used for human habitation is suffering from an infectious disease to which the Act applies, then, unless such building is a hospital in which persons suffering from an infectious disease are received,

(a) *The head of the family* to which such inmate (referred to as the patient) belongs, and in his default the nearest relatives of the patient present in the building or being in attendance on the patient, and in default of such relatives every person in charge of or in attendance on the patient, and in default of any such person the occupier of the building, shall, as soon as he becomes aware that the patient is suffering from an infectious disease to which the Act applies, send notice thereof to the medical officer of health of the district.

(b) Every *medical practitioner* attending on or called in to visit the patient shall forthwith, on becoming aware that the patient is suffering from an infectious disease to which the Act applies, send to the medical officer of health for the district a certificate stating the name of the patient, the situation of the building, and the infectious disease from which, in the opinion of such medical practitioner, the patient is suffering.

The certificate must be in the form prescribed by the Local Government Board, and must be given in respect of a case of infectious disease to which the Act applies occurring in any building, not belonging to His Majesty, used for human habitation, unless such building is a hospital in which persons suffering from an infectious disease are received; and also in a case occurring in any ship, vessel, or boat not belonging to His Majesty or to a foreign Government, or in any tent, van, shed, or similar structure used for human habitation and not belonging to His Majesty, in like manner as nearly as may be as if it were a building. The penalty for default in sending the certificate is a fine not exceeding 10s. The forms of certificates are to be supplied gratuitously by the local authority, who will also pay for every certificate sent by a medical practitioner in accordance with the requirements of the Act a fee of 2s. 6d. if the case occurs in the course of his private practice, or a fee of 1s. if the certificate is given in respect of a case occurring in his practice as medical officer of any public body or institution. Where a medical practitioner attending on a patient is himself the medical officer of health of the district, he will be entitled to the fees to which he would be entitled if he were not such medical officer. It seems that if a medical practitioner in the proper exercise of his discretion certi-

fies that a patient is suffering from any disease, his opinion cannot be subjected to review by the local authorities, and the fee to which he is entitled under the Act must be paid.

The infectious diseases to which the Act applies in all cases include the following: small-pox, cholera, diphtheria, membranous croup, erysipelas, the disease known as scarlatina or scarlet fever, and the fevers known by any of the following names: typhus, typhoid, enteric, relapsing, continued, or puerperal. If the authority of any district to which the Act extends desire that the Act shall in their district apply to any infectious disease other than the above, they may from time to time, by a resolution, order that the Act shall in their district apply to such disease.

It is of importance to note that the provisions of the Act apply to every ship, vessel, boat, tent, van, shed, or similar structure used for human habitation, in like manner as nearly as may be as if it were a building, and that a ship, vessel, or boat lying in any river, harbour, or other water not within the district of any local authority within the meaning of the Act, will be deemed for the purposes of the Act to be within the district of such local authority as may be fixed by the Local Government Board, and where no local authority has been fixed, then of the local authority of the district which nearest adjoins the place where such ship, vessel, or boat is lying.

Prevention of Infectious Disease.—The Infectious Disease (Prevention) Act, 1890, is an adoptive Act, and is not in force until the prescribed forms for adopting it have been gone through; but it may be adopted in part only. The diseases to which it applies are the same as in the case of the Act of 1889, and the subjects to which it relates are—

(a) The inspection of dairies, and the prohibition of the supply of milk therefrom in cases where it appears that infectious disease is attributable to, or likely to be caused by, the consumption of milk so supplied;

(b) The cleansing and disinfection of premises, bedding, clothing, &c., for the purpose of preventing or checking infectious disease;

(c) The retention, removal, and burial of the bodies of persons who have died from infectious disease;

(d) The detention in hospital of persons suffering from infectious disease, who would, on leaving the hospital, be without proper lodging; and

(e) The provision of temporary shelter and attendance for members of families who have been compelled to leave their dwellings for the purpose of the dwellings being disinfected.

As during recent years attention has been very prominently directed to milk as a source of infection, it is not surprising to find that this Act confers powers which are considerably in advance of any which the legislature has previously given to local authorities. On this subject the Act provides that in case the medical officer of health of any district in which the section is adopted is in possession of evidence that any person in the district is suffering from infectious disease attributable to milk supplied within the district from any dairy situate within or without the district, or that the consumption of milk from the dairy is likely to cause infectious disease to any person residing in the district, he shall, if authorised in that behalf by an

order of a justice having jurisdiction in the place where the dairy is situate, have power to inspect such dairy, and, if accompanied by a veterinary inspector or some other properly qualified veterinary surgeon, to inspect the animals in the dairy. If, on such inspection, the medical officer of health is of opinion that infectious disease is caused by consumption of the milk supplied from the dairy, he is to make a report to the authority whose officer he is. This report must be accompanied by any report that may be furnished to him by the veterinary inspector or veterinary surgeon above mentioned. The authority may thereupon require the dairyman to appear before them to show cause why an order should not be made requiring him not to supply any milk from the dairy within the district until the order has been withdrawn. If he fails to show such cause, they may make the order.

The Act also contains some important provisions in regard to the use of public conveyances for the conveyance of the bodies of persons dying of infectious disease, the disposal of infectious rubbish, and the cleansing and disinfection of houses and articles therein likely to retain infection. On the last subject the Act provides that where the medical officer of health of any local authority, or any other registered medical practitioner, certifies that the cleansing and disinfecting of any house, or part of it, and of any articles in it likely to retain infection, would tend to prevent or check infectious disease, the clerk to the authority is to give notice in writing to the owner or occupier that the house or part of it, and any articles in it likely to retain infection, will be cleansed and disinfected by the authority at the cost of the owner or occupier, unless he informs the authority, within twenty-four hours from the receipt of the notice, that he will do the cleansing and disinfection, to the satisfaction of the medical officer of health, within a time fixed in the notice. If, within twenty-four hours from the receipt of the notice, the person to whom it is given does not inform the authority that he will so do the cleansing and disinfection, or if, having so informed the authority, he fails to have the work done within the time fixed in the notice, the house or part of the house and articles are to be cleansed and disinfected by the officers of the authority under the superintendence of the medical officer of health, and the expenses incurred may be recovered from the owner or occupier in a summary manner. But where the owner or occupier of the house or part of a house is unable effectually to cleanse and disinfect it, and any article therein likely to retain infection, the officers of the authority, with the consent of the owner or occupier, may undertake the cleansing and disinfection at the cost of the authority.

No person may retain unburied, elsewhere than in a public mortuary, or in a room not used at the time as a dwelling-place, sleeping-place, or work-room, for more than forty-eight hours, the body of any person who has died of an infectious disease, unless he shall have obtained the sanction in writing of the medical officer of health, or of a registered medical practitioner.

In connection with this Act it is of the greatest importance to bear in mind that it is an adoptive Act not only as a whole, but as to sections, so that before any particular enactment is acted on, steps should be taken to ascertain that it has been properly put in force in the particular district.

Dwellings of the Working Classes.—

Some very important alterations of the law were made by the Housing of the Working Classes Act, 1890, the principal of which related to (1) unhealthy areas, and (2) unhealthy dwellings.

As to unhealthy areas, it is provided that where an official representation is made to the local authority by the medical officer of health, that within a certain area in their district either (a) any houses, courts, or alleys are unfit for habitation; or (b) the narrowness, closeness, and bad arrangement or the bad condition of the streets and houses or groups of houses within such area, or the want of light, air, ventilation, or proper conveniences, or any other sanitary defects, or one or more of such causes, are dangerous or injurious to the health of the inhabitants either of the buildings in the said area or of the neighbouring buildings, and that the evils cannot be remedied otherwise than by an improvement-scheme for the re-arrangement and reconstruction of the streets and houses within such area, the local authority, if satisfied of the truth of the representation, shall pass a resolution to the effect that such area is an unhealthy area, and proceed to make a scheme for the improvement of the area. Before the scheme can come into operation it has to be confirmed by provisional order, which requires the sanction of Parliament.

The law relating to the assessment of compensation payable under an improvement scheme in respect of any house or premises situate in an unhealthy area, provides that in such cases evidence shall be receivable by the arbitrator to prove—(1) That the rental of the house or premises was enhanced by reason of the same being used for illegal purposes, or being so overcrowded as to be dangerous or injurious to the health of the inmates; or (2) that they are in such a condition as to be a nuisance within the meaning of the Acts relating to nuisances (which are defined by section 2 as meaning as respects any urban sanitary district in England the Public Health Acts, and as including any local Act which contains any provisions with respect to nuisances), or are in a state of defective sanitation, or are not in reasonably good repair; or (3) that they are unfit, and not reasonably capable of being made fit, for human habitation; and that if the arbitrator is satisfied by such evidence, then the compensation—(a) shall in the first case, so far as it is based on rental, be based on the rental which would have been obtainable if the house or premises were occupied for legal purposes, and only by the number of persons whom they were under all the circumstances of the case fitted to accommodate without such overcrowding as is dangerous or injurious to the health of the inmates; and (b) shall in the second case be the amount estimated as the value of the house and premises if the nuisance had been abated, or if they had been put into a sanitary condition, or into reasonably good repair, after deducting the estimated expense of abating the nuisance or putting them into such condition or repair, as the case may be; and (c) shall in the third case be the value of the land, and of the materials of the buildings thereon.

As to unhealthy dwellings, the Act gives some powers that are far in advance of any previous law. It is declared to be the duty of every local authority to cause to be made from time to time inspection of their district with a view to ascertain whether any dwelling-house therein is in a state so dangerous

or injurious to health as to be unfit for human habitation, and if, on the representation of their medical officer of health or any of their officers, or information given to them, it appears that any dwelling-house is in such state, to forthwith take the proceedings against the owner or occupier for closing it under the Public Health Act, 1875.

Under the Public Health Act it had hitherto been necessary that the proceedings should be taken with a view to the abatement of a nuisance, and that the works requisite to abate the nuisance complained of should be specified. This, however, is no longer the case, as summary proceedings may be taken for the express purpose of causing the dwelling-house to be closed, and appropriate forms are prescribed for this purpose.

The effect of the closing order will be to prohibit the using of the premises for the purpose of human habitation until, in the judgment of the court, they are rendered fit for that purpose. In making it the court may impose a penalty not exceeding 20*l*.

Where a closing order has been made in respect of any dwelling-house, and has not been determined by a subsequent order, the sanitary authority, if of opinion that the house has not been rendered fit for human habitation, and that the necessary steps are not being taken with all diligence to render it so fit, and that the continuance of any building being or being part of the dwelling-house is dangerous or injurious to the health of the public, or of the inhabitants of the neighbouring dwelling-houses, are required to pass a resolution that it is expedient to order the demolition of the building. Unless the building is promptly made fit for human habitation it must be demolished. Some important extensions of the law were made by the Housing of the Working Classes Act, 1900, by which county councils were empowered to acquire land and erect dwellings outside their districts, and thus relieve the congestion in towns.

COUNTY OF LONDON.—The law as set forth above relates to the whole of England and Wales, but does not apply to the county of London, for which there are several special Acts of Parliament. The Local Government Acts, 1888 and 1894, the Metropolitan Local Management Acts, the Metropolitan Building Acts, the Public Health (London) Act, 1891, the London Building Act, 1894, and the London Government Act, 1899, and some other acts, prescribe the law relating to the constitution, powers, and duties of the London County Council and the corporate boroughs into which all the former local vestries and boards are now merged; and also the general provisions as to the laying out of streets, the construction of buildings, and the regulation of all matters of sanitation and public health. It would be impossible to go into these provisions here, but in many respects they are the same as those above described for the provinces.

W. A. CASSON.

SANITATION; SANITARY SCIENCE (*sanus*, sound).—Sanitary science treats of the principles on which health is maintained and disease prevented. The principal agencies which contribute to this result will be found treated of in this work under the following headings: BATHS; DISINFECTION; EXERCISE; FOOD, POISONOUS; HYDROTHERAPEUTICS; IMMUNITY; INFECTION; MORTALITY; PERSONAL HEALTH; PHYSICAL EDUCATION; PUBLIC HEALTH; QUARANTINE; SANITARY LAW;

SEA-AIR and SEA-BATHS; VACCINATION; and VITAL STATISTICS.

SAN REMO, on the Riviera, Italy, near the French Frontier.—A well-sheltered, dry, mild, equable winter climate. Mean winter temperature, 54° F. Early vegetation. *See* CLIMATE, Treatment of Disease by.

SANTA AQUEDA, in Spain.—Cold sulphated and chalybeate waters. *See* MINERAL WATERS.

SANTA BARBARA, in Southern California.—A very mild, equable climate, on the Pacific coast. Temperature—mean annual, 61° F.; winter mean, 54°. Rainfall, 16 inches. Used for phthisis and other pulmonary affections. *See* CLIMATE, Treatment of Disease by.

SANTA FÉ.—The capital of New Mexico, at an altitude of 7,013 feet, in a dry and arid region. Lacks equability of temperature. Mean annual temperature, 48° F.; relative humidity percentage, 45. More suitable for a winter than a summer residence for invalids. It is principally recommended as a winter residence for pulmonary affections on account of its combining a certain degree of warmth with altitude. *See* CLIMATE, Treatment of Disease by.

SAPRÆMIA, SEPTICÆMIA, and PYÆMIA.

The production of pus by the micro-organisms of sepsis never occurs, even in its most localised form, without an accompanying general effect on the blood. This effect is due to the toxins produced by the microbes in the septic area, and absorbed into the circulation. The absorption of toxins of various kinds is in itself the cause of the primary symptoms of all septic disease; but there may occur simultaneously an invasion of the blood by the bacteria which produce the toxins. The most pronounced form of septic disease is that in which the bacteria, starting from some local lesion, have invaded the circulation, and set up at various points secondary areas of inflammation more or less similar to the original focus.

General septic poisoning has accordingly been classified into three main forms.

(a) *Sapræmia*, in which only the toxins of the bacteria are absorbed, the bacteria themselves remaining confined to the primary area of inflammation. In practice, accordingly, when the original wound or abscess is surgically cleansed, the symptoms of intoxication rapidly vanish. A familiar example is seen in one form of puerperal fever, which yields to simple douching of the uterus. In the production of the bacterial poison, a large variety of bacteria may be involved, both pathogenic and putrefactive.

(b) *Septicæmia*.—In this form the bacteria of sepsis, as well as their toxins, find their way into the circulation. To demonstrate this condition clinically, it is necessary to remove portions of the blood, add them to suitable culture-media, and incubate at 37° C. Since, as a rule, few colonies appear, it is desirable to obtain a fairly large sample of blood. The bacteria in this condition, though present in the blood, do not give rise to localised abscesses apart from the original seat of infection. A good example of septicæmia is seen in the blood of rabbits which have had a subcutaneous injection of the exudate of croupous pneumonia. There is

only a small amount of localised inflammation at the site of the injection ; but before death the blood of the animal is swarming with diplococci. There are, however, no secondary foci of suppuration.

(c) *Pyæmia*, the third type of generalised sepsis, occurs when the original focus has given rise to a number of secondary centres of inflammation, situated at various points in the course of the circulation. The secondary foci develop into abscesses.

The classification of the three conditions is a practical one, and is based on the conception that we may regard the diseases as belonging to one type, i.e. essentially toxin-poisoning, and recognise a certain progressive character in the three forms. It must be admitted, however, that our present knowledge does not justify us in adopting this conception without qualification. A case of pyæmia is not necessarily more severe than a case of septicæmia, and we are only partly acquainted with the factors which determine the form which generalised sepsis may take in any particular instance.

SYMPTOMS.—Clinically, *sapræmia*, since it consists solely in the absorption of toxins, distinguishes itself from the other forms by the rapidity of its onset. *Post-mortem* and dissecting-room wounds, though of minute size, often begin to cause severe symptoms within twenty-four hours. There is local pain and swelling. The pulse increases in rate, the temperature rises, and there is a feeling of general weakness and disinclination for mental or bodily exertion. If at this stage the wound is cleansed, especially if the edges are cut away and free drainage encouraged by fomentations, the general and local symptoms rapidly vanish as a rule. In cases which proceed to further stages, rigors occur. There may be profuse perspiration, or a dry, hot skin. The tongue is at first red, and later becomes brown. There is often diarrhœa and vomiting, with slight jaundice. Sometimes there is great tenderness of skin, and even petechiæ may be observed. Emaciation proceeds rapidly. Later the temperature falls, and coma comes on. Death occurs in the second or third day of the disease ; but the patient may remain for some days in the so-called 'typhoid' condition, when death supervenes from exhaustion.

In *septicæmia*, the symptoms being also due to the effect of toxins are not essentially different from those of *sapræmia* ; but the process naturally tends to progress more slowly at first. It generally assumes one of two forms—a mild and an acute. When acute there is, as in cases of *sapræmia*, firstly a stage of violent reaction, followed by that of the 'typhoid' type. The toxins in septicæmia are manufactured both in the local focus and in the blood, and in later stages the disease may become very rapid.

Pyæmia defines itself still later than *sapræmia* or septicæmia. *A priori*, one would expect that the toxin-producing power of the microbe is relatively less, and its power of invading the tissues more developed, as compared with the bacteria of *sapræmia*. The symptoms of pyæmia are observed, generally speaking, within a week after the date of the wound or injury from which it originates. The symptoms of intoxication are the same as in *sapræmia* and septicæmia. The distinctive character of the disease is due to the occurrence of septic thrombosis and embolism in the circulation. This leads to the formation of secondary abscesses and to purulent inflammation of the serous membranes in the large

cavities and in the joints and tendon-sheaths. The brain, lungs, liver, kidneys, spleen, heart, and muscular tissues are the seat of thrombosis, embolism, and abscess-formation, and the symptoms due to such local effects correspond with the particular form of the lesion, e.g. apoplexy, delirium, angina pectoris, dyspnœa, paraplegia, &c. &c. A rash similar to that of scarlet fever is not uncommon, and hæmorrhages in the skin are frequently seen. The patient in fatal cases dies about the tenth day. Mild forms, sometimes called cases of multiple abscess, occur, in which the patient after developing a few metastatic abscesses in the subcutaneous, or some other non-vital area, recovers completely.

The diseases which give rise to pyæmia are chiefly the following : empyema, fetid bronchitis, infective compound fractures, ulcers of the intestine, infected wounds, and, somewhat rarely, infective periostitis.

PATHOLOGY.—The discussion of the structural changes to which septic invasion of the blood gives rise is naturally chiefly concerned with those seen in cases of pyæmia, and historically it is the form of septic disease which has been most closely investigated in this respect. The name was originally introduced by Piörriy in the attempt to explain all forms of general septic infection as due to the intravasation of pus. It was shown subsequently by Virchow and others, however, that it is impossible to group all the phenomena of pyæmia as the effects of a single cause. There are, it was pointed out, at least two series of effects, firstly the mechanical, taking the form of a block in the circulation, and due to thrombosis and embolism, and, secondly, an irritant effect due to the action on the cells in various tissues of some substance which has diffused into the blood from the infected areas. This was called the 'infecting substance,' and is now known to consist of microbes and the chemical poison derived from them.

The sequence of changes is the following. The effect of an inflammatory area on the veins in the neighbourhood is to cause thrombosis. The thrombus may be hard or soft. In any case it contains within itself the microbes and leucocytes which have the power of disintegrating it, e.g. by digesting it, and converting it into a mass of pus and broken-up septic clot (see *ABCESS*, p. 7). This material is in a condition to travel in the blood-vessels, and passes into the still patent part of the vessel to form emboli. The infected emboli settle in a small blood-vessel, and set up abscess-formation. Virchow pointed out, however, that on anatomical grounds this is not the sole explanation. We find, for example, in pyæmia, that large serous cavities are infected, and it is impossible to conceive that the inflammation of the whole surface of a lung could be due to mechanical emboli plugging the vessels. The 'infecting substance' itself causes inflammation, and acts along with the emboli, and in particular gives rise to conditions such as pleurisy and purulent synovitis. See *EMBOLISM*, p. 453.

Certain other changes are to be found within the blood in septic poisoning which fall to be described here. The cells of the blood show evidence of the direct effect of the poison. Commonly we find a marked leucocytosis of the ordinary inflammatory type, the polymorphonuclear neutrophile cells being over 80 per cent. of those present (p. 156). This immigration of leucocytes is due to the chemiotactic effect of the toxins. On the other hand, cases

cur in which there is not only no increase but even a diminution. The explanation of this fact is suggested by certain experiments with the pneumococcus of Fraenkel by Tschistowitch, who found that when he injected rabbits with a coccus of moderate virulence, leucocytosis occurred in the blood; if he used a coccus of exalted virulence, no such effect followed. See p. 157.

An interesting line of investigation is to be found in the study of the aggregation of leucocytes into masses in septic conditions of the blood. It is occasionally mentioned in the older descriptions of pyæmia that the leucocytes were observed in clumps in the blood (Sédillot, Virchow). Recently Metschnikoff has shown that in normal animals a serum can be obtained experimentally with a specific power of bringing about this form of agglutination. From a number of observations the present writer made on cases of pyæmia, he is inclined to regard this phenomenon as one of importance among the changes in pyæmic blood, particularly because a possible mode of explaining the factors which determine the occurrence, in one case of pyæmia, and in another of septicæmia, is suggested by it.

As regards the red corpuscles, it has been observed that the necrobiotic changes described by Ehrlich and Maragliano as occurring in various forms of anæmia occur in pyæmia also. Reference will be made later to Koch's discovery of the aggregation of red corpuscles to form emboli in the pyæmia of rabbits.

Virchow observed in a number of cases that the blood had lost its alkaline reaction. One of the most marked cases had suffered from puerperal pyæmia. The exact value of this observation is still to be decided. The acid present was not a volatile fatty acid.

There has been very little research carried out in the blood as a whole in pyæmia. Roscher in 1894 published the most important contribution to our knowledge of this subject. He showed that with the progress of the disease there is a diminution in the number of red blood-corpuscles per mm., and a proportional decrease in the percentage of hæmoglobin. There is also a diminution in the percentage of solid residue left when the serum is dried. This residue, he finds, cannot diminish below one-half without fatal results ensuing.

The lowering of the percentage of hæmoglobin may be due to mere increase in plasma, or to a true destruction of the red cells. Since, however, (1) hæmoglobinuria somewhat rarely occurs in pyæmia, and (2) the reduction of the residue after drying is marked, it seems probable that we have to deal with both changes in the blood, viz. hydræmia as well as hæmolysis.

Such is the general clinical and pathological picture of the disease which we are able to form on our present-day knowledge. It is unnecessary to go into much detail regarding the affections which appear in the various organs, since it is not an inflammation in a particular site, but the association of groups of inflammatory changes which is the significant fact in the diagnosis of pyæmia. The lung is naturally the most frequent site of abscess. The kidney from the structure of its capillaries is also very liable to abscess-formation. In areas of terminal arteries, as in the spleen and kidney, we find septic infarctions. Where there

are serous surfaces we have an inflammation affecting the whole, or large parts of the membrane. Thus synovitis, pleurisy, pericarditis, are frequent occurrences in the disease. In some cases, especially in children, bronchitis or enteritis is a prominent feature. In the brain, septic meningitis occurs, and also abscesses, which are especially frequent in the occipital lobe. A special form of pyæmia is septic or malignant endocarditis. See p. 652.

The ætiology of the condition was very partially understood until the discovery of the agency of bacteria as the 'infecting substance,' and poison-producer in the disease. The bacteria chiefly concerned in septicæmia and pyæmia are the *Streptococcus pyogenes*, *Staphylococcus pyogenes aureus*, and *Staphylococcus pyogenes albus*. Many records have been published describing cases due to unusual micro-organisms, e.g. *Micrococcus tetragenus*, *Pneumococcus*, *Bacillus septicus putridus*, and *Bacillus hæmorrhagicus*. It is, however, unnecessary to do more than point out the possibility of such cases, their interest being in the light they throw on cases of inexplicable origin. See ABSCESS; and BACTERIA.

A considerable amount of experimental investigation has been carried out with a view to defining the nature of the toxic bodies which give rise to the phenomena of the disease. It was shown, in the first instance, that cultures of pus-producing microbes, when sterilised by heating, are still, if injected, capable of producing suppuration. The dose necessary for this purpose was, however, found to be very much larger than that of the living culture. It was accordingly concluded (Janowski) that in such an experiment it was necessary to introduce the quantity of toxic substance which is produced in the animal by the living culture before suppuration is brought about. When the effects were more closely investigated it was found that a distinction had to be drawn in regard to the bacteria of sepsis, as in the case of other bacteria, between intra- and extra-cellular poisons. The extra-cellular poisons, it was found, are easily destroyed by boiling; whereas the toxicity of the poisons in the bodies of the microbe is relatively less affected by this temperature. The intra-cellular poisons are by far the more important of the two, and are specially characterised by their chemiotactic power of attracting the leucocytes to the site of inflammation, and thereby producing pus-cells. In Koch's comparative study of infective septic diseases, he discovered that it is possible to reproduce experimentally in animals the conditions corresponding to sapræmia, septicæmia, and pyæmia. Thus, if blood which has putrefied for a few days be injected subcutaneously into a mouse (five drops) it dies in four to eight hours, and on *post-mortem* examination there is found no invasion of bacteria into blood or tissues, nor any sign of inflammation. The animal has died from simple intoxication. If the same fluid be injected in smaller amount, there is no poisoning. The animal remains apparently healthy for twenty-four hours, and then develops symptoms of disease, and dies in forty to sixty hours. There is slight subcutaneous œdema; the spleen may be enlarged; but further signs of disease are wanting on *post-mortem* examination. This animal is infected throughout, and from any organ infective material can be obtained which produces the same condition in other mice

into which it is inoculated. By using another kind of putrid fluid, Koch produced in rabbits a general infection, and from the blood of the animal successful inoculation could be performed. The *post-mortem* changes, local and general, were those of pyæmia, and in particular there were metastatic deposits in the lungs and liver. Koch further observed that the micrococci were deposited in masses on the side of the blood-vessels, and these masses showed a power of causing the adhesion together of red blood-corpuscles on the side of a vessel. The micrococci have thus the power in themselves of giving rise to the formation of thrombi and emboli. This power of aggregating the blood-corpuscles Koch regarded as a characteristic of the micrococcus with which he was experimenting, and to the formation of these masses he attributes the metastatic deposits. He obtained subsequently a true septicæmia in rabbits in which secondary deposits did not occur, and which had not the power of enclosing the red corpuscles in the masses which formed in the blood-vessels.

We see, therefore, that in mice and rabbits the various types of the general septic disease can be reproduced—the difference depending on the specific character of the microbes inoculated. It has also been found that the bacilli of mouse-septicæmia produce no effect on the rabbit, even when inoculated in very large doses. In this again we have evidence of the specific nature of the process. On the other hand, it has been shown in experimenting with the diplococcus of pneumonia that a variety of septic diseases can be produced by selecting for inoculation various types of animals, e.g. rabbits, sheep, dogs, &c. The specific character of the septic disease depends in this series of experiments on the kind of animal employed.

With these facts, pathological and bacteriological, before us, we have to discuss now more particularly the occurrence of general sepsis in the human subject. It must be admitted that in spite of the clinical and experimental investigations which have been shortly referred to in the foregoing paragraphs, we have not before us material to enable us to say decisively why a given case becomes pyæmic, while another is septicæmic. F. Gärtner recently studied two cases of septicæmia, and two of pyæmia, each originating in uterine infection, and each showing the same anatomical lesions of inflammation round a septic focus. In each case he found both streptococci and staphylococci. Gärtner does not propose an answer to the question, but concludes with the demonstration of the very close resemblance of the four cases so far as the origin was concerned. The micrococcus had in each case invaded the blood.

The path of entrance taken by the microbes is clear when a septic wound can be demonstrated. In many cases, however, the mode of invasion is obscure. These cases are sometimes called cryptogenic. Fischl carried out an investigation of great interest on septic infection of infants. He showed that the apparently primary gastro-enteritis and capillary bronchitis are in reality part of a general condition of septicæmia or pyæmia. In a recent *post-mortem* examination, the writer found this condition in the lungs of an adult. The abscesses contained a pure growth of *Staphylococcus pyogenes albus*. Fischl mentions that nine out of fourteen cases he examined showed this coccus in pure cultivation. He regarded the source of infec-

tion as the air or the food. Grawitz has shown that in certain abnormal conditions the general resistance of the tissues to the invasion of microbes is less than that in force when the subject is healthy. Some time ago the present writer performed a *post-mortem* examination on a patient who had shortly before death accidentally fractured a number of ribs. The patient also suffered from acute mania. Round each site of fracture an abscess had developed, although there was no discoverable lesion of the surface by which infection might have gained entrance to the tissues. This case illustrates the effect of disease and injury in lowering resistance to invasion. Gottstein has carried out an experimental investigation on this subject. He injected guinea-pigs with the bacillus of chicken-cholera, a microbe to which they are relatively immune, and at the same time gave them a dose of hydracetic subcutaneously. They died with abscess-formation and inflammatory change in the serous cavities. The point of importance in this experiment according to Gottstein is that the disintegration of red blood-corpuscles by the hydracetic sets free ferments which intoxicate the animal, and thus breaks down the resistance of the tissues. He also experimented on the breaking down of resistance by using pyrogallol, which dissolves the red blood-corpuscles, and came to the conclusion that in cases of sepsis the resistance of the whole organism is broken down by the poison, and this is followed up by an invasion of bacteria.

In considering this question in relation to pyæmia in the human subject we come upon a very difficult pathological problem. In 1886 Stephen Paget showed that a special relationship holds between abscess of the liver and fracture of bone, and that necrosis of bone has a similar relation to abscess of the kidney. Again, pleurisy and pericarditis are more common after injuries to limbs than after injuries to head and trunk. Abscess in the heart is more common in pyæmia involving the lower limbs than in any other. The lungs are the most favourite site of abscess. Among muscles, the pectoral are the most frequently affected, while the calf-muscles are the next in frequency. Another favourite site of inflammation is the synovial sheath of the tendons on the back of the left hand; another, the back of the left eye. The result of Paget's investigations is difficult of interpretation on any theory of local or general resistance. Marmorek has, however, attempted to arrange the observations on pyæmia in a general theory of lines of defence. Organs most liable to abscess-formation in pyæmia are those which are weakest in defence. The anti-bacterial coefficient of any organ is in inverse ratio to the number of bacteria found in it. The anti-bacterial power of a tissue is associated with the number of active living cells found in it. On this theory the first line of defence for the organism is the skin and subcutaneous connective tissue. The second is the lymphatic glands. The third line of defence is the blood. After this, organs are liable to suffer in inverse ratio to their anti-bacterial power. This theory is somewhat difficult to apply to the actual problems of septicæmia and pyæmia in the human subject.

TREATMENT. — As regards treatment of these conditions, little remains to be said. The surgical cleansing of all primary foci, and in some cases of pyæmia of secondary foci also, is the first step which should be taken (*see* CELLULITIS). In the

next place, if the sepsis be due to the streptococcus, the anti-streptococcus serum may be employed. The evidence as to the value of this new therapeutic agent has not yet accumulated in sufficient quantity to be decisive (*see* SERUM-THERAPEUTICS). Medical treatment of the symptoms is to be strenuously carried out. The temperature is to be controlled by antipyretics, and quinine is the drug most recommended for this purpose by the clinical authorities. The maintenance of the strength by suitable diet and stimulants is also of the greatest importance. In some of the cases where treatment has been successful the period of convalescence has been very prolonged. J. LORRAIN SMITH.

SARATOGA, in Saratoga County, New York, U.S.A.—Alkaline chalybeate and muriated alkaline waters, containing traces of iodine and bromine. The springs of Ballston, a few miles from Saratoga, are of a like character. *See* MINERAL WATERS.

SARCINA (*sarcina*, a pack or bundle).—This is a morphological term applied to various species of micro-organisms belonging to the group of Schizomycetes, which, developing by fission in three planes at right angles to one another, form more or less cubical aggregates of 4, 8, 16, 32, or 64 cocci, having the appearance of corded 'bales' or 'packets.' They are non-motile, do not form spores, and retain the stain after treatment by Gram's method. When cultivated upon artificial media many species are chromogenic, the characteristic arrangement in cubes is lost, and only diplococci and tetrads are to be demonstrated microscopically. *See* BACTERIA.

So far as is known at present, the sarcinæ are not pathogenic, but merely occur in diseased organs as casual saprophytes.

The most important species of sarcina met with in human pathology are the following:—

1. **Sarcina ventriculi**.—This species is of frequent occurrence in the stomach, and in the vomit of gastric dilatation from pyloric obstruction; in some cases of gastric ulcer and carcinoma without dilatation; and in rare cases of gastric catarrh.

Sarcina ventriculi. Showing sarcinæ and starch-granules in vomited matter. $\times 400$ diam.

Their presence, however, is not sufficiently constant to be of much diagnostic value, and is certainly not pathognomonic of a dilated stomach, as has been supposed. Their appearance is usually associated with a state of fermentation of the gastric contents, which appear frothy, and are of an acid reaction and smell; but it would seem that the organism is

not the actual cause of the condition, for cases are recorded of their occurrence in vomit that showed no signs of fermentation; while the introduction of pure cultivations of sarcinæ into the stomach is not followed by fermentative changes in its contents.

Sarcinæ are easily detected under the microscope. A drop of liquor potassæ added to a fragment of vomit on the glass slide, and covered with thin glass, is sufficient to display their characteristic appearances. The constituent cells are about 1.9μ in diameter.

2. **Sarcina pulmonum**.—This species has been described as occurring in certain lung-states associated with suppuration. It is said readily to induce ammoniacal decomposition of the urine when introduced into this fluid; and in one case appeared to contain starch or cellulose in its composition.

Sarcinæ are also stated to have been found in the fæces, in the ventricles of the brain, in hydrocele-fluid, in gangrenous intestines, and in cholera-stools. W. H. ALLCHIN.

SARCOCELE (*σάρξ*, flesh; and *κύλη*, a tumour). A name for any solid enlargement of the testes. *See* TESTES, Diseases of.

SARCOMA (*σάρξ*, flesh).—A form of new-growth. *See* TUMOURS.

SARCOPTES SCABIEI.—A synonym for *Acarus scabiei*. *See* ACARUS.

SATURNISM (*saturnus*, lead).—A synonym for lead-poisoning. *See* LEAD, Poisoning by.

SAWYER'S CRAMP.—*See* OCCUPATION-DISEASES; and WRITER'S CRAMP.

SCABIES (*scabies*, scab, mange).—SYN.: Itch; Fr. *Gale*; Ger. *Krätze*.

DEFINITION.—A simple inflammation of the skin, produced by the irritation of the *Acarus scabiei* and the scratching of the sufferer. The disease is contagious, as the parasite is easily transferred from one person to another. *See* ACARUS.

DESCRIPTION.—The parts of the body most likely to be attacked are the soft skin between the fingers, and on the flexor side of the wrists and elbows; the lower part of the abdomen, buttocks, and penis; and in women the mammæ; in children the feet and legs, in addition to the other parts of the body already mentioned, are very liable to be attacked. The acarus generally attacks both sides of the body symmetrically, and in adults is never met with in the skin of the face or scalp; but any other part of the body may be affected.

The eruption produced by the acari and by scratching, is attended by itching, especially at night, and resembles a scattered eczema; and the extent and severity of the disease will depend chiefly on its duration. The most characteristic feature for the purposes of diagnosis is the scabies-burrow, which resembles roughly an old pin-scratch. Examined closely, it has a dotted and beaded appearance with ragged dirty edges at its entrance, where the roof of the cuniculus has been worn away by rubbing. At the distant end of the burrow may be sometimes seen the parent-acarus, which is easily extracted by inserting the point of a pin along the burrow and touching the acarus, which immediately adheres to the pin, and may thus be removed for the purpose of examination.

DIAGNOSIS.—The following points serve to distinguish scabies: (1) the particular parts attacked as just indicated; (2) the eruption, which consists of scattered and isolated papules and vesicles, and more rarely pustules, with their tops more or less torn by scratching; (3) the history of the case, and especially of contagion; (4) the presence of the scabies-burrow; and (5) the demonstration of the acarus by means of the microscope.

TREATMENT.—The usual plan of treating scabies is by the use of either (1) sulphur-ointment; or (2) sulphur-baths or lotions. The former is the more effectual method, although the latter may be occasionally preferred. In order to cure an ordinary case of scabies, it is simply necessary that the patient, before going to bed, should thoroughly apply and well rub in the sulphur-ointment to every part of the body, excepting the skin of the face and scalp; and in order to keep the ointment in contact with the skin, he should sleep in his under-clothes, such as drawers, jersey, socks and gloves, and in the morning take a warm bath and put on clean clothes. The process should be repeated for three or four nights, after which the ointment should be used every night for a week or ten days to those parts of the body only which are especially attacked by the disease. It is not necessary to boil the under-clothes, ordinary washing and ironing is quite effective.

The ointment should contain a drachm of sulphur to an ounce of benzoated lard, but for young children an ointment of about half this strength is most suitable. A common mistake is to use a strong sulphur-ointment for many weeks, thus producing an irritable state of skin, which is mistaken for a continuation of the scabies.

If a sulphur-bath be preferred, it may be made by dissolving half a pound of sulphurated potash in thirty gallons of water. It is necessary to repeat the bath several times at intervals of a few days.

If it be desired to treat scabies by a lotion, Vlemingx's solution may be used. It is made by boiling five gallons of water with a quarter of a pound of quicklime and half a pound of sulphur until three gallons are left. This lotion is effective, but it is apt to irritate the skin, and is not so generally useful as the sulphur-ointment.

R. LIVEING.

SCALD.—An injury to any part of the body caused by the action of moist heat, either in the form of steam or of a hot fluid. See HEAT, Effects of.

SCARIFICATION (*scarifico*, I make an incision). This is an operation in which small superficial incisions are made, through either the skin or mucous membrane, to allow the escape of blood, as in wet-cupping, or of serous fluid, in relieving dropsical effusions; or to liberate the teeth, as in difficult dentition.

SCARLATINA.—A synonym for scarlet fever. See SCARLET FEVER.

SCARLET FEVER.—**SYNON.**: Scarlatina; Febris scarlatina; Fr. *Scarlatine*; Ger. *Scharlach*.

DEFINITION.—A febrile infectious disease, of which the characteristic symptoms are a punctate erythematous rash and a sore-throat. During convalescence the skin desquamates and certain complications often occur, the most important being inflammation of the ears, kidneys and joints.

GEOGRAPHICAL DISTRIBUTION.—At the present day scarlet fever is confined chiefly to the temperate zones, being more or less endemic in Europe (especially the north-western countries and Russia), in the northern of the United States, and in parts of South America. It is not common in Australia, and is rare in the tropics, even among the European population.

ÆTIOLOGY.—One of the most remarkable facts in connection with the ætiology of scarlet fever is the decrease in its mortality during the past thirty years. Thus the average annual death-rate per million living for England and Wales has fallen from 982 (1861-5) to 241 (1886-90).

Since 1874 there has been an almost unbroken decline in the death-rate; nor has this decrease been confined to England and Wales. It has been observed in Scotland, Ireland, Sweden, Norway, Denmark, Germany, and many large continental cities and towns; there is also evidence of the same decrease in the United States of America. Some writers have suggested that it is in part due to lessened prevalence (morbidity); but that this is far from being an important factor is shown by a study of such notification-statistics as are forthcoming, not only from this country, but also from abroad. J. T. Wilson has shown that the lessened mortality is due chiefly to the lessened fatality (case-mortality). This has been observed not only in hospital cases, but also in all cases in nearly every town where notification has been in force. That there has been of recent years a change of type in the disease will hardly be denied by any one who has had sufficient opportunity for clinical observation. The most severe forms are less frequent than they formerly were. This lessened severity may perhaps be due partly to such causes as improved sanitation and a more general use of hospitals; but there are also at work factors which are unfortunately quite unknown to us, so that we have no guarantee that we have seen the last of virulent scarlet fever. At present the fatality in London is less than 4 per cent.; but as an instance of the height to which it can rise, it may be mentioned that in Stockholm in the year 1870 it was no less than 28.8 per cent.

Age.—Scarlet fever is a disease mostly of children, especially of those from two to ten years of age. The fourth year is the period of greatest susceptibility. Below one and over twenty-five the disease is uncommon. The fatality is highest during the first year, and though falling with each year, yet is high up to the fourth. It then remains low up to the fortieth, after which it again rises slightly.

Sex.—Though at all ages more cases are actually met with among females, yet males are somewhat more susceptible to the disease. The fatality is also higher among males.

Race.—The dark races of mankind are less susceptible than the white.

Seasonal prevalence.—The London notifications show that usually the number of cases begins to rise in June and, with a slight check in August, continues to rise to a maximum in October. It is slightly lower during November and falls somewhat quickly during December and January. The minimum is reached in March or April. The fatality, however, is highest during January, February and March, and lowest from July to November.

Dissemination.—Scarlet fever is highly infectious. The infection is spread chiefly in a direct manner by individuals suffering or convalescent from the

disease; but it is often conveyed by means of infected articles (clothing, books &c.) and by third persons. The virus, when harboured in clothing or other fomites, remains active for long periods of time.

The disease can also be spread by means of a milk-supply. In some outbreaks the origin of the contamination of the milk has not been ascertained; in others it has been found in a case of scarlet fever occurring among persons concerned in the collection or distribution of the milk; while in a third group it has been shown that cows from which the milk was obtained were the subjects of a certain disease of the udders, skin and viscera.

From the evidence collected in the last group of cases, it appears to be certain that cows suffer from a disease capable of giving, through their milk, scarlet fever to human beings. There is reason also to believe that swine suffer from a disorder which must be regarded as scarlet fever.

It is probable that the aggregation of children in schools is not without influence on the prevalence of the disease. At any rate there is every year a fall in the notifications, previously on the rise, during the summer holidays of the School Board in London, the rise being resumed soon after the re-opening of the schools. This fall is most marked at the school ages (3 to 13).

Defective hygiene influences scarlet fever in respect not to its prevalence, but to its type; so that insanitary surroundings aggravate an attack and favour complications. So far no definite effects have been traced to the influence of soil, rainfall or temperature, unless we except its rarity in the tropics.

MORBID ANATOMY.—Beyond the local faucial lesions there is little to be seen *post mortem* by the naked eye. During the eruptive period a microscopic examination of the skin reveals hyperæmia and œdema of the cutis vera, with proliferation of the cells of the Malpighian layer of the epidermis. Besides the cervical, other lymphatic glands, especially the mesenteric, may be enlarged, and occasionally the Peyer's patches are slightly inflamed. In septic cases the spleen may be enlarged. During the acute stage the kidneys present little, if any, changes, at the most a slight infiltration of the interstitial tissue with leucocytes. In cases of nephritis the inflammatory changes affect chiefly the glomeruli and the interstitial tissue of the cortex.

PATHOLOGY.—There can be little doubt that the essential cause of scarlet fever is some kind of micro-organism, which probably gives rise to a general infection, and not to a local one with secondary toxæmia, as in diphtheria. The disease has been produced by the inoculation of healthy individuals with the faucial and buccal secretions of a scarlet-fever case.¹ More than one observer has believed that he has discovered the specific organism. According to Klein it is a particular streptococcus, which he isolated in 1886 from the diseased udders and viscera in an outbreak attributable to the milk of certain cows on a farm at Hendon, and which he has since that date found in the blood, tissues, and skin of cases of human scarlet fever. This organism, which is the same as one subsequently described by Kurth under the name of *Streptococcus conglomeratus*, differs, according to Klein, from the *Streptococcus pyogenes*. When

grown in broth the fluid remains clear, and the organism forms one large or several small conglomerate masses at the bottom of the vessel or test-tube. Gordon has found it in most of several cultivations taken from the tonsils of patients in different stages of scarlet fever, but never in the aural, and rarely in the nasal discharge: a peculiar fact when we remember that there is good reason for believing that the nasal discharge is particularly infectious. If this micro-organism be injected into calves or mice, general infection takes place; and the organism in question can be recovered from the blood and tissues of the affected animals. There is no clear proof, however, that this general infection is the same disease as human scarlet fever; and we have further to remember that it has been established that in the latter disease cocci are present in the fauces and elsewhere, some of which are the cause of the septic and suppurative complications, though not of the disease itself. The *S. conglomeratus* (as well as another coccus to be immediately referred to) may after all be only one of these accidental organisms. More recently, Class has described an organism which he believes to be the cause of scarlet fever. It is a diplococcus, which, when grown on glycerine-agar, to which 5 per cent. of sterilised black garden-earth is added, assumes the form of a large gonococcus. He states that he has isolated this organism from the fauces, blood, and desquamating skin of scarlet-fever cases. If the blood of a patient convalescent from scarlet fever be added to the culture-medium, the organism is prevented from growing. The diplococcus is pathogenic to mice, guinea-pigs, and swine. In white swine it gives rise to an attack of fever with an erythematous rash which is followed by desquamation. The disease thus produced by inoculation is infectious, so that other animals of the same kind contract the disease naturally from those artificially infected.

In connection with these experiments it may be mentioned that Behle has reported an outbreak of a disease in pigs, which accompanied an epidemic of severe scarlet fever among children in the same locality. The chief symptoms were angina, erythema, albuminuria, and desquamation. A healthy pig was inoculated with the blood of a child suffering from severe scarlet fever in this epidemic, and the animal was fatally attacked by a disease which had exactly the same symptoms.

It must be left to future investigators to decide which, if either, of the two organisms above mentioned is the specific cause of scarlet fever.

CLINICAL HISTORY.—The incubation-period is usually of two or three days' duration. It is not infrequently shorter, but rarely longer. Probably it never exceeds five days.

Prodromal period.—The most constant symptoms are vomiting, a rise of temperature, headache, and sore-throat. Occasionally, especially in adults, a sore-throat is complained of for a day or two before the other symptoms appear. In mild cases there may be no vomiting; on the other hand, in a few cases vomiting may be so frequent as to induce within a few hours a serious state of collapse, even though the subsequent course of the attack is by no means severe. A rigor is rare, but the patient may feel chilly. Children are restless and refuse their food. The pulse-rate usually rises considerably (120 to 140 a minute). The tongue is coated with a white fur; sometimes there is diarrhœa.

¹ These inoculations were most unjustifiably performed by Stickler, of Orange, New Jersey, U.S.A., in the hopes of finding a protective virus in the secretions.

After a few hours the initial vomiting ceases, but the other symptoms persist till the appearance of the rash, which usually comes out within twenty-four hours from the onset of the attack. In not a few of the mild cases the rash is observed as early as any of the symptoms; on the other hand, in some of the most severe, its appearance is delayed till the third, fourth, or even fifth day. As a rule the character of the prodromal symptoms corresponds with the severity of the attack.

Three forms of the disease can be distinguished clinically; but it must be remembered that between them are gradations, so that no hard and fast line can be drawn.

1. *Scarlatina Benigna*, or Simple Scarlet Fever.—In this form all the symptoms are of moderate intensity. The rash, though it usually invades the trunk and limbs, may be limited to a portion of the former, or may be absent altogether. It lasts for three or four days, but sometimes for a much shorter time, even for less than a day. While the rash is coming out the temperature is moderately elevated (100° to 102° F.). With the fading of the rash the temperature gradually falls, and reaches the normal at the end of three to seven days. There may be no sore-throat, and the fauces may appear normal. But sore-throat may be present with little if any visible lesion; though there is usually tonsillitis with or without inflammation of the soft palate and pharynx. These structures may be smeared over with loose muco-purulent exudation, and slight superficial ulceration may occur. The cervical glands are moderately enlarged and painful in cases where the tonsils are inflamed. Complications and sequelæ occur less frequently than in the more severe forms of the disease; yet it must not be forgotten that most serious affections, such as nephritis and otitis, do occasionally follow even the mildest cases, especially when neglected. Desquamation may be delayed till the end of three weeks, and may be partial or absent.

2. *Scarlatina Anginosa* (Septic Scarlet Fever).—The prodromal symptoms are usually of some severity; but occasionally a case, at first of the benign form, after a few days becomes septic and presents graver symptoms. The distinguishing feature of this variety is the faucial affection. There is, in the first instance, general and acutely painful inflammation of the fauces, which may be swollen to such a degree as to impede deglutition or respiration. A viscid secretion fills the mouth and naso-pharynx; and pultaceous, sometimes membranous, exudation forms upon the tonsils and palate. The nasal passages are inflamed and blocked; and a discharge, at first thin and watery, later muco-purulent, pours from the nostrils, excoriating the adjacent skin. The cervical glands are much enlarged, of doughy consistency, and very painful. Often, too, the skin and subcutaneous areolar tissue are inflamed, and there is a hard, brawny swelling, extending in the most severe cases from one ear below the chin to the other (bull-neck). The throat is acutely painful. The faucial œdema may resolve without any subsequent lesion; but usually necrosis takes place, and yellow or grey sloughs are seen, the separation of which leads to ulceration of the tonsils, uvula, soft palate, or pharynx. In extreme cases the necrosis is so extensive as to involve the whole of the soft parts of the fauces; in those less severe portions only slough, as the uvula or a tonsil. Occasionally a portion of one or both anterior pillars sloughs, and

oval perforations are left; this local sloughing is probably caused by the pressure of the swollen tonsil against the œdematous anterior pillar. The angle between the base of the uvula and the anterior pillar on each side is a favourite seat of ulceration. The ulceration is usually slow to heal; sometimes, indeed, far from healing, it spreads, and may travel downwards past the root of the tongue to the epiglottis and larynx, in which case symptoms of laryngeal inflammation gradually manifest themselves.

The processes described above are usually in non-fatal cases of two or more weeks' duration. The temperature is at first persistently high, 102° to 104° F., or higher. After a few days or a week or two it becomes irregular; and four or five weeks may elapse, while the faucial ulceration is healing, before it resumes the normal. The pulse-rate is much increased in frequency (140 to 160). At first the pulse is full and bounding, later it is small and feeble. The rash persists for a week or ten days. Most often it is vivid and extensively distributed, but occasionally it is patchy, and it may be altogether wanting. The tongue, at first coated with thick white fur, quickly peels, and assumes the 'strawberry' appearance. Later it becomes dry and dirty. Sordes collect along the gums and lips, and the angles of the mouth are excoriated. Stomatitis with ulceration is not infrequent. In a few cases there is extensive excoriation round the anus.

During the first week or so the patient is restless, sleepless, and delirious. Wasting is rapid and extreme; and vomiting and diarrhoea, especially the latter, are often met with. Desquamation commences about the end of the first week, and is profuse. There is also considerable loss of hair. Complications are common, especially otitis media and suppurative lesions.

Death in septic scarlet fever usually occurs during the second or third week, but it may be delayed for another week or two, the patient dying of exhaustion after the febrile period is over. But in such cases it will be observed that the pulse-rate remains high, and the faucial ulceration shows little, if any, signs of repair. In non-fatal cases recovery is very tedious.

3. *Scarlatina Maligna* (Toxic Scarlet Fever).—The symptoms are severe from the onset: repeated vomiting, a very frequent pulse, a high temperature (104° to 105° F.), and prostration being the most prominent. The rash is usually profuse. The face is of a yellowish hue and waxy appearance. The sore-throat is slight, there being moderate inflammation of the fauces. The cervical glands are little if at all enlarged. The rapidity of the heart's action soon leads to cardiac failure, and there is cyanosis with sighing respiration. Muscular tremor is present. The tongue is covered with dry fur. At first the patient is delirious, but soon becomes comatose; in a few cases, however, the mental condition remains clear to the end. This form of scarlet fever almost invariably proves fatal, death taking place on the fifth or sixth day; occasionally earlier, even on the first or second, before the rash has come out or fully developed.

Hæmorrhagic scarlet fever, in which there are hæmorrhages into the skin and from the mucous membranes, is very rare at the present day.

Other forms of scarlet fever.—Cases are not infrequently met with, especially during epidemics, in which the patient presents no other symptoms

beyond those of a slight febrile attack with sore-throat. Instances have been recorded when such cases have given rise to typical scarlet fever in susceptible persons; hence they may be regarded as *abortive* cases.

Occasionally cases are observed where the chief feature of the attack is a continued fever of four or five weeks' duration, the throat-affection being moderate and the constitutional symptoms not, as a rule, severe. These may be regarded as *prolonged* examples of the benign variety. Occasionally, however, they terminate fatally from exhaustion or some complication.

As for the so-called *surgical* and *puerperal* varieties, the writer sees no reason for believing that they differ from the ordinary forms of the disease. Children the subjects of 'surgical' affections are not more likely to take scarlet fever than those who are suffering from 'medical' ailments; except, perhaps, in the case of burns or scalds. Scarlet fever of the puerperal state is rarely met with, and not necessarily severe.

SYMPTOMS.—The *rash* of scarlet fever consists of two elements, a diffuse erythema and very small distinct spots or puncta. The puncta generally appear earlier than or as soon as the erythema, though occasionally the erythema is visible for some hours before the spots. The papular or punctate element outlasts the erythema, especially in those regions where the skin is naturally coarse, as on the extensor surfaces of the extremities, where the papules often consist of inflamed hair-follicles. The rash is usually most intense about the flexures of joints, where, as also upon the upper part of the chest, it may be petechial. It appears first on the neck and chest, but quickly spreads to the rest of the trunk and upper and lower extremities. It affects also the skin just in front of and behind the ears, reaching the temples; but it spares the scalp, face, palms, and soles. In marked cases it attains its height on the third or fourth day, after which it gradually fades. The colour varies from a faint pink to a bright vermillion. In cases where the circulation or respiration is embarrassed it is of a dusky red or even purplish hue. In some cases of the septic form the rash is morbilliform on the extremities and consists of papules and macules, affecting also the palms and soles; but on the trunk the ordinary character of the rash is retained, and the face is not affected. The face, though always free from rash, is often deeply flushed, with the exception of the area round the nostrils and mouth, which is pale (circum-oral ring of pallor). Occasionally the conjunctivæ are injected.

The rash is most intense in the severe forms of the disease; the skin may then be slightly tumid, especially on the hands, causing the sensation of a tight glove. Miliaria are sometimes seen in large numbers on the wrists and hands, less frequently on the trunk and legs.

The *tongue* is at first coated with white creamy fur, composed chiefly of epithelium in process of being shed. The papillæ are enlarged, and stand out as red points projecting through the white fur. The latter separates along the sides and tip of the organ, and in patches on the dorsum. When all the fur has separated the tongue is left red, raw and moist, with the enlarged papillæ standing out as glistening points. This is the condition known as 'strawberry tongue,' which, though occurring more often in scarlet fever than in any other disease, is

by no means constant in or confined to that affection.

Desquamation is one of the most characteristic features of scarlet fever. It usually commences about the seventh to tenth day; in mild cases, however, it may be delayed to the end of the third week, while in severe it is observed as early as the second or third day. Peeling usually starts about the ears and cheeks; but very soon it is observed on the neck, upper part of the trunk and arms, and lastly upon the rest of the trunk and extremities. Occasionally it commences in the pubic region. The process is usually completed within from six to eight weeks, but occasionally within a shorter period. The palms and soles are the last places to become free from desquamation; indeed, they may go on peeling for three or four weeks after the rest of the skin has become clear. Desquamation is usually universal, even though the rash is not. It is most free in cases where the rash has been intense and the fever acute; but it may occur and even be profuse when there has been little or no rash. On the other hand, a few mild cases of scarlet fever, even with a considerable rash, do not apparently peel at all.

The desquamation assumes three forms, which may often all be observed in the same patient. In the first, the most common and diagnostic variety, the process commences with the appearance of minute white points on the skin, caused by the separating horny layer of the papillæ. These white points are rubbed off and give place to small 'pinhole-like' rings, which, enlarging, coalesce with one another so as to give rise to a general flaky desquamation. This 'pin-hole' form does not occur on the face, where the peeling is almost always of the second variety, which consists of fine branny or powdery scales, such as may follow any erythema. This kind is observed especially in infants and mild cases. Lastly, large irregular areas of epithelium may be shed entire, leaving the skin pink and tender, but very rarely raw. In such cases the skin may separate from the fingers like a glove. Very seldom are the nails cast off.

The *urine* during the febrile period is high-coloured, somewhat diminished in quantity, and deposits urates. It may contain a trace of albumen, which is not necessarily a herald of any subsequent nephritis.

The *skin* is usually dry, and in severe cases frequently hot. During convalescence, after peeling, patients are subject to frequent perspiration.

COMPLICATIONS.—*Otitis media* is the most frequent of all the complications. It is met with most often in the septic form of scarlet fever, arising during the period of the faucial ulceration. But it may occur in mild cases and during convalescence. Children under five are most prone to it. Otitis nearly always arises through the inflammation spreading up the Eustachian tube from the throat. Usually the first sign is a thin watery discharge from the ear, but earache, tenderness of the ear, and pyrexia may precede the discharge for a day or two. After a time the discharge becomes muco-purulent and often offensive. There is nearly always some loss of hearing, which, however, is usually neither complete nor permanent.

In the majority of cases under appropriate treatment, the discharge ceases in a few weeks. Occasionally a mastoid abscess or more serious

complications (inflammation and necrosis of the temporal bone, especially the mastoid process, meningitis, pyæmia, and cerebral abscess) occur early in the course of the otitis. More commonly, however, they are met with after the disease has become chronic. Complete deafness, usually due to implication of the internal ear, with in young children consequent dumbness, is at the present day very rare.

Inflammation of the cervical glands is most common in the septic form of the disease during the acute stage, but it may occur in the milder cases and during convalescence. Suppuration often results. Sometimes, especially during the early period of the attack, the *skin and subcutaneous tissue of the neck* are also involved, and extensive sloughing, especially of the latter, takes place. In a few cases, mild as well as severe, all the superficial glands can be felt to be enlarged, as in rubella.

Nephritis is the most characteristic complication or sequel of scarlet fever. Its incidence varies much in frequency in different years, from 2 to 17 per cent. It is more common in children than in adults, especially between the ages of five and ten. Males are more liable than females. It follows mild nearly as often as severe attacks; and there is no reason to suppose that it is due to 'cold' or to allowing the patient to get up too soon. It most commonly sets in at the end of the third, or the beginning of the fourth, week, but may occur as early as the tenth day, or as late as the sixth or seventh week, when the patient has almost recovered from the attack of scarlet fever. It is rarely seen earlier or later than these periods. The onset is usually sudden. There is headache, nausea or vomiting, a rise of temperature (100° to 105° F.), and occasionally shivering. The urine next voided is found to be smoky in appearance and to contain albumen, blood-discs, and renal casts. The amount of urine is at first much diminished; the pulse-rate is accelerated (but the arterial tension is not usually increased), the tongue is furred, and the bowels are confined. In most cases the acute symptoms pass off in two or three days, but there is irregular pyrexia, which may persist for a week or two, the temperature-curve being very like that of pyæmia. At first there may be slight puffiness about the eyes and ankles, and a little œdema of the loins and scrotum, but pronounced anasarca is uncommon, save in neglected cases. Recovery is gradual, and is not complete for five or six weeks.

In some cases the onset of nephritis is insidious, and its presence is revealed only by albuminuria. Hence the great importance of frequently examining the urine of the convalescent patient. Later more definite signs may appear. These cases are apt to be very tedious and to resist treatment.

In both forms convulsions, coma, and occasionally other cerebral symptoms (squint, retraction of head, &c.) may occur. Acute nephritis sometimes leads to persistent albuminuria, less often to chronic nephritis. Quite half the cases are accompanied by some other complication, such as otitis, adenitis, and secondary sore-throat. Death occurs in about 7 per cent. of the cases, and is due to uræmia, œdema of the lungs, acute cardiac dilatation, or some additional complication, such as pneumonia.

Albuminuria may occur during the febrile period, at the end of which it disappears, not being usually followed by nephritis. Transient albuminuria of

two or three days' duration is not uncommon during convalescence, especially about the time when nephritis is expected. Such cases should always be regarded with suspicion and treated as commencing or slight and transient nephritis, which indeed they may be.

Arthritis may occur under three different pathological conditions. The *first* and most common is the so-called *scarlatinal rheumatism*. This arises about the end of the first week, especially in cases of the septic form of scarlet fever. It is most commonly met with in adolescent patients, particularly females. In many of the patients a history of a previous attack of rheumatic fever can be obtained. The small joints are affected rather than the large, especially the joints of the wrist and hand. Occasionally the inflammation shifts about from one joint to another. Neither the local nor the constitutional symptoms are as a rule severe, pain in the joints and slight pyrexia being often the only signs. The disease is of short duration. Slight relapses may occur. Suppuration is very unusual.

The *second* form of arthritis is rare. It also occurs in the septic variety of scarlet fever. One or two of the large joints become inflamed and suppurate; but there is no evidence of general pyæmia, and under appropriate treatment recovery ensues.

Lastly the joints, usually several, may suppurate in consequence of general pyæmia, either in septic scarlet fever or as the result of such a complication as disease of the ear. The onset of the joint-affection is often very insidious.

Convalescent children are often troubled with *eczema*, especially of the skin about the ears and around the nostrils and lips; a discharge from the ear or nose is sometimes the cause of this. *Rhinitis* may arise during convalescence; in many of the cases the diphtheria-bacillus can be found in the discharge.

Secondary or accidental rashes are not uncommon, especially a papular and blotchy erythema, affecting chiefly the extensor surfaces of the limbs in septic cases. Sometimes such a rash appears to be due to nephritis.

Diphtheria is not infrequently found associated with the acute stage of scarlet fever; but it more often arises during the period of convalescence. It is worth noting in connection with this complication that more than one observer has found the Klebs-Loeffler bacillus in a certain proportion of scarlet-fever cases during the first few days of their illness, even though the fauces have not presented any appearance suggestive of diphtheria.

Of the remaining complications the least infrequent are *tonsillitis*, occurring during convalescence; *ulcerative stomatitis*; and *bronchitis* and *bronchopneumonia*, the two latter especially in very young children. Still more uncommon are *laryngitis*, *lobar pneumonia*, *pleurisy*, *endo- and peri-carditis*, *cardiac dilatation*, *ophthalmia*, *pyæmia*, *meningitis*, *chorea*, *jaundice*, *peritonitis*, and *mania* (p. 770). Both *relapses* and *second attacks* may occur; the former are met with in less than 1 per cent. of hospital cases.

DIAGNOSIS.—Difficulties arise because some cases, usually mild attacks, present little or no rash, or because a rash closely resembling that of scarlet fever is met with in other conditions. In mild cases of the former kind a diagnosis from other throat-affections is often impossible without the occurrence of rheumatism, nephritis or the characteristic de-

desquamation. In severe cases without a rash (usually mistaken for diphtheria) initial vomiting, a very frequent pulse, continuous high temperature, delirium, much œdema and deep ulceration of the fauces, are signs of scarlet fever. Of the latter kind the prodromal rashes of measles, varicella and small-pox, the rashes of measles, rubella, and of septic conditions, rashes following the administration of certain drugs and the use of purgative enemata, and certain idiopathic erythematous rashes, are not infrequently sources of error. The most difficult to differentiate is the scarlatiniform variety of rubella (Clement Duke's 'Fourth disease'), which is exceedingly like scarlet fever of the mild form, especially if there be little or no sore-throat. If the rash affects the face scarlet fever can be excluded. Initial vomiting, a peeling or a 'strawberry' tongue, and circum-oral pallor, are in favour of scarlet fever. The universal though moderate enlargement of the superficial lymphatic glands is in favour though by no means diagnostic of rubella. In some cases, however, it is necessary to suspend the diagnosis, which may be cleared up by the occurrence of other cases or by the onset of some characteristic complication, or by subsequent 'pin-hole' desquamation.

In the other diseases mentioned above a careful attention to the symptoms other than the rash and a consideration of the conditions under which the rash has occurred will usually lead to a correct diagnosis.

The presence of Filatow's or Koplik's spots on the buccal mucous membrane is of great value in the diagnosis of measles (morbilli).

PROGNOSIS.—The younger the patient the more unfavourable the prognosis, the disease being more fatal in children under five than at other ages. The benign form rarely gives rise to any immediate anxiety, but it is to be remembered that most serious complications (e.g. nephritis, or otitis media, with necrosis of the temporal bone), often follow the very mildest attacks. All cases of the septic form should be viewed with apprehension; and nearly every case of scarlatina maligna is fatal.

Of individual symptoms the following are the most grave: repeated vomiting; great frequency of the heart's action maintained for several days (in adults a very frequent pulse is of graver import than in children; but in some cases of septic scarlet fever in children the temperature falls and the local disease of the fauces, though not healing, does not get worse, yet the pulse-rate remains high, and this is an unfavourable sign); coma; sighing respiration, and an alteration of the respiratory rhythm.

In cases of nephritis, scanty urine and coma are very unfavourable events, but most cases of convulsions recover. Those cases of nephritis, which commence abruptly, are usually of shorter duration than those whose onset is insidious. Chronic nephritis does not often ensue.

Patients who are the subjects of tubercular lesions are very liable to have them aggravated by an attack of scarlet fever, and also to develop nephritis and other complications.

TREATMENT.—In the mild forms of the disease it will be sufficient to spray or irrigate the fauces and nasal passages with a solution of boric acid (saturated) or chlorate of potassium (gr. xv ad 3j) or weak chlorine-water, three or four times a day. In cases where the throat-lesions are severe these solutions may be used every two or three hours. If

there is much exudation alkaline solvent applications are useful, such as solution of bicarbonate of sodium.

All the above solutions may be used as gargles, sprays, or irrigations, being applied in the latter case with a ball- or Higginson's-syringe; but in some cases it will be found to be more efficacious to swab out the fauces occasionally with pledgets of cotton-wool lightly wrung out of the solution. In septic cases weak solutions of carbolic acid (1 in 40) or corrosive sublimate (1 in 2,000) may be employed, also by means of swabs. When there is much pain the patient is usually relieved by the application of warm fomentations or poultices to the neck, but in some instances more relief is afforded by sucking ice.

During the febrile stage the diet should consist of milk and water, beaten-up eggs, arrowroot, cornflour, &c.; a little beef-tea, and chicken- or mutton-broth may also be allowed. When the temperature has regained the normal level bread and butter, fish, eggs, custard and milk-puddings may be added, and gradually, after a few days, fish, poultry, and meat. Lemonade, soda-water, tea and coffee, and such fruit as oranges and grapes may be taken at any time. The room should be well ventilated and kept at a temperature of 55° to 60° F. The patient may be allowed to sit up in blankets after the temperature has been normal three or four days, provided no complications have arisen; and after another week he may be fully dressed. If the weather is warm and otherwise favourable he may in another three or four days be permitted to go out of doors for a short time daily. A warm bath every evening, beginning at the time of the patient's first getting up, will facilitate desquamation.

Mild cases need no physic, unless it be for the purpose of securing a daily action of the bowels, for constipation must certainly be avoided. The best treatment for pyrexia and delirium is the tepid wet-pack or sponging with tepid water. Even if the temperature be not very much lowered by these measures, sleep is induced. Of drugs, anti-febrin in small doses repeated at intervals if necessary is the most safe, and has much the same effect. When there is prostration stimulants are required, such as strychnine, alcohol, ether, or ammonia.

For the treatment of complications, the reader is referred to the special articles dealing with these affections. If the patient is treated at home, all precautions should be taken to prevent the spread of infection. The patient should be kept isolated for at least six weeks, and should be released at the end of that time only if no complication exists and peeling (except of the soles) has finished. Otherwise the patient should be kept isolated for a longer period. Patients discharged from fever-hospitals, and also those treated privately, sometimes remain infectious for a longer period than six weeks, even though they appear to have quite recovered their health, as is shown by their giving rise to fresh cases (the so-called 'return cases') when they are allowed to mix with susceptible children. The most infectious condition appears to be the nasal discharge, which often persists for a long period. It is most desirable that this as well as other discharges and morbid conditions should be cured before the patient is allowed to associate with other children. *See* also pp. 769 and 474.

SCHOTT-TREATMENT, The.—During recent years much interest has been centred in the Schott-treatment of disorders of the heart and circulatory system as practised at Nauheim, by the employment of its baths with special exercises. Nauheim, which has long been noted for its famous Springs, lies at an altitude of over 400 feet on the N.E. slope of the Taunus range. Some of its waters are used for drinking, others for baths. Thus the Kur-Brunnen and the Karls-Brunnen Springs are chiefly for internal administration; the Ludwigs-Brunnen and the Schwalheimer-Brunnen are valuable table-waters. Of the waters employed for bathing purposes the Great and Little Sprudel (82°–95° 5' F.) are rich in carbon dioxide and the chlorides of sodium—2 to 3 per cent.—and calcium, with traces of salts of other metals such as iron, arsenic, barium, and lithium.

The varieties of baths employed are as follows: (1) Simple brine-baths, weak and strong; (2) Effervescent brine-bath, rich in CO₂ and salts; (3) Effervescent current-, surf- or wave-bath. The kind, number, strength and temperature of the baths prescribed are controlled, and vary with each case, according to the judgment of the physician after his observation of the symptoms and physical signs presented by the patient. After each bath a sufficient period of repose is enjoined, and the bath is generally intermitted every few days. Many patients go to Nauheim for the baths only, others for the baths and 'resistance' exercises.

The Schott-treatment at Nauheim has been as intemperately decried by some as it has been unwisely recommended by others. A prudent and judicious selection of cases is imperative, inasmuch as important physiological effects on metabolism and on the circulatory system result from its employment. See p. 1470.

The Schott-treatment by gymnastic exercises is employed in conjunction with the Sprudel baths. It consists of a scientifically planned system of voluntary movements on the part of the patient combined with resistance offered by the hand of the physician or skilled attendant. By such measures, carefully graduated, commencing failure of compensation in cardiac valvular disease is often successfully combated; a variety of cardiac symptoms ameliorated; and some cases of the heterogeneous group of functional cardiac disorder much benefited.

Clinical experience shows that some cardiac cases are benefited by rest, others by exercise, some by drugs, some by hydrotherapeutic measures. Hence before prescribing a course of the Schott-treatment at Nauheim, it is necessary to ascertain the condition of the cardiac muscle, the degree of dilatation and the condition of the arterial walls.

The change to bracing air and sunshine, the regulated mode of living, the carefully planned daily

routine, the avoidance of any source of fatigue, the psychical influences counteracting introspection, and—greatest change of all—the change to repose of mind and body, all constitute important factors of the treatment and possibly explain why the Schott-treatment at Nauheim has been more successful than its imitations elsewhere.

SCIATICA.—SYNON.: Fr. *Néuralgie Sciatique*; Ger. *Hüftweh*.

DEFINITION.—Neuralgia in the district of the sciatic nerve.

Sciatica is signalised by paroxysmal pain in any or all of the following localities: the buttock; the back of the thigh; the knee; the front, back, and outside of the leg; and the whole foot except its inner border. The condition is frequently of peripheral origin, and is then dependent on inflammation of the nerve-trunk. Or it may arise independently, to all appearance, of any local cause in the nerve itself, and is then probably caused by some impairment of nutrition of a nerve-centre. As the diagnosis of interstitial neuritis from neuralgia is as yet not certainly established, the two conditions will be considered together.

ÆTIOLOGY.—*Predisposing causes.*—The predisposing causes of sciatica are the rheumatic and gouty diatheses; anæmia; the toxic influences of malaria, chronic alcoholism, syphilis, and lead; inherited neurotic disposition; fatigue; and a damp and cold climate.

Exciting causes.—These include exposure of the limb to a draught of cold air for some long time, which is a common source of the affection; sitting on a cold or damp seat; over-walking; strains; concussion of the spine; the encroachment of morbid growths; blows upon or wounds of the nerve-trunk; malignant and other tumours of the pelvis; disease of the vertebræ or pelvic bones; the pressure of the gravid uterus; rheumatic or gouty inflammation of the sciatic nerve, or of one or other of its branches; syphilitic periostitis, causing a swelling which presses upon the trunk or some branch of the sciatic nerve; gumma in the sheath of the nerve.

In chronic rheumatoid arthritis of the hip-joint the sciatic nerve may sometimes be felt to have hard, knotty swellings upon it, apparently arising from a chronic perineuritis. This is associated with very obstinate sciatica.

Sciatica affects especially the middle age of life, from forty to fifty years, is rare in youth, and but seldom commences in elderly persons. It is at least four or five times as common in men as in women.

The violent manipulation of an unskilful professional rubber, employed to treat a dull aching in the sciatic region, may bring about acute sciatica.

ANATOMICAL CHARACTERS.—Nothing certain is as yet known of the character of the lesion in cases of neuralgia proper manifested in the district of the sciatic nerves.

The few changes which have been observed *post mortem*, or after removal of a portion of the nerve, in cases of sciatica have been in the direction of

thickening of the sheath of the nerve, with exudation and sometimes small hæmorrhages, the result of inflammation. It has happened, however, that in cases which during life have been supposed to be examples of neuritis, no trace of the inflammatory process has been found in the nerve itself.

SYMPTOMS.—Usually after more or less of vague discomfort in the affected limb, deadness, tingling, stiffness, or some such abnormal sensation, pain occurs in some part of the district already indicated. This is variously spoken of as shooting, darting, screwing, tingling, or burning; and the sufferer will often map out with precision the course of various branches of the nerve as the seat of his distress. Sometimes the leg is described as being numbed, or as if it were going to burst. Occasionally the feeling resembles a very faint shock of a battery. As is characteristic of neuralgia generally, the pain may be apparently spontaneous in origin, while in certain cases it is also liable to be aggravated by movement, but in no case is it *only* excited when muscular contraction takes place. It may either occur in paroxysms, with intervals of complete immunity varying from minutes to hours; or there may be more or less continuous suffering, with frequent and violent exacerbations. Throbbings or pulsations of the pain are often described. It is not, as a rule, accompanied by pyrexia. When the pain is at its height, a powerlessness of the muscles of the limbs is apt to be experienced, and this not simply on account of the distress of moving, but from an actual paresis, dependent possibly upon a depressing influence communicated to the motor centres; or, should the condition be one of neuritis, due to interruption of nervous channels. From a like cause affecting the vaso-motor fibres the limb will feel cold, not only subjectively, but to the touch.

Tender points may be met with in all, but more often in some few only, of the following situations: The posterior inferior spine of the ilium; about the middle of the dorsum of the ilium; about midway between the tuber ischii and trochanter major; the fold of the buttock; head of the fibula; behind each malleolus; in the popliteal space. There is commonly some cutaneous anæsthesia in some part of the limb, and sometimes replacing this there will be found hyperalgesia of certain patches of skin. The tactile sense proper is lowered at these points, while the sense of temperature, especially for heat, is often heightened. At the same place a weak voltaic current is felt as extremely and quite abnormally painful. Cramp of the calf-muscles is common. It is often impossible for the patient to sit, owing to the tenderness of the nerve-trunk near the tuber ischii. The act of putting on a stocking, stooping, or sneezing gives rise to great pain.

There are great differences in the course and character of the affection. In some persons the disease from the first presents the characters of a chronic affection. There is never pain sufficient, for example, to prevent sleep, and it may not arrive at such a degree of severity as to interfere much with locomotion. Indeed the sufferer may experience a certain amount of relief from moving about. But the patient is worn by a more or less constant aching in the district of the sciatic nerve, which becomes especially marked after long sitting, as on a railway journey, and most of all if the seat be somewhat hard. Fatigue of body and mental worry have great effect, in such cases, in intensifying the

symptoms, which, on the other hand, may almost entirely disappear in circumstances favourable to improved health and mental exhilaration. Sciatica of this type is prone to attack the middle-aged, to be permanent, and to acquire additional intensity with advancing years. In contrast with such cases are those which from the first exhibit the characteristics of an acute affection. The pain is so agonising that no posture affords relief, sleep is impossible, the general health greatly suffers, and the patient is placed completely *hors de combat*. The disease may last for weeks or months without material intermission, the patient being confined helplessly to his bed; and when at length the symptoms subside, the period of convalescence may be very prolonged. Or after some weeks of acute suffering, improvement may take place, only to be followed by a relapse, which is even more violent than the original attack.

Although the recumbent position is commonly that which is least irksome to the patient, yet it will happen that after a night passed in sleep attempts to move the affected limb cause it to be more painful than after walking, and there is a distressing stiffness about it.

In some persons the disease appears once, in a very severe form, it may be at a comparatively early period of life, and never recurs. In many, however, it tends to recurrence, and with such persistence that the patient will speak of 'his sciatica' as a companion which is always present, though occasionally for a term out of sight. Or it may alternate with attacks of typical neuralgia in other parts of the body; or be replaced by various functional disorders of the nervous system, accompanying an excess of uric acid in the urine.

The disease (doubtless in its neuritic form) is liable to be accompanied by considerable muscular atrophy of the limb, and a quasi-paralytic condition, which, though capable of improvement, may, exceptionally, leave the patient more or less lame for the rest of his life. Much more often the wasting which has accompanied the acute symptoms gradually ceases as these subside, and during the somewhat prolonged convalescence the limb is restored to its original size, and the lameness is no longer observed. Sciatica often follows, and is sometimes accompanied by lumbago.

DIAGNOSIS.—There are three conditions of the muscular system which are apt to be confounded with sciatica: (1) Myalgia from over-exertion of the flexor muscles at the back of the thigh. Here the pain will be found at the points of insertion of the muscles, and is only felt during their action. (2) Rheumatism in the muscles from exposure to cold. Here, again, the pain is not spontaneous, as in sciatic neuralgia, but is always dependent on muscular action. (3) A low inflammation of the loose bursal tissue which separates the large muscles of the thigh, brought about, it is probable, by the presence of some morbid material conveyed by the lymphatic vessels with which the spaces are in direct communication. Uric acid may apparently cause this affection. Sacro-iliac disease may be distinguished by its always occurring in youth; by the pain being confined to the sacral neighbourhood; and by the limb being lengthened at an early period. From hip-joint disease, especially in the slow insidious form which it sometimes takes, sciatica is not always distinguished with facility. The paroxysmal character of the pain, presence of tender

points, absence of result from forcible movement of the joint, and absence of characteristic position or shortening of the limb, will best serve for diagnosis. The lameness in sciatica may lead to the idea of spinal paraplegia, from which the disease may be distinguished by the perfect integrity of the other limb, as well as by the paroxysmal pains, tender points, and the history showing that the powerlessness was secondary to the pain. From the darting pains in the thigh consequent on renal calculus sciatica may be easily distinguished by careful examination.

The affection may be limited to a single branch, and when this is the terminal portion of the anterior tibial nerve supplying the big toe, there is a *primæ facie* resemblance to gout. It may be distinguished from this, however, by noting the absence of heat, swelling, redness, or pain on moving the joint; and the presence of a small spot, at which alone pressure is extremely painful.

Syphilitic periostitis, with inflammation of the sheath of the sciatic, may be distinguished from malignant disease by the effect of large doses of iodide of potassium. Sciatica may be distinguished from the lightning-like pains of tabes dorsalis by the presence of the patellar tendon-reflex. Should, however, the anterior crural nerve be affected with neuritis coincidently with the great sciatic, the knee-jerk may be temporarily lost. The Achilles-tendon reflex may be lost in cases of sciatic neuritis, and also, according to Babinski, in examples of purely neuralgic sciatica. It is well to remember that sciatica, properly so called, is an unilateral affection. Should it be described as affecting *both* lower extremities coincidently, examination will show that the supposed sciatica is either tabes dorsalis, or neuritis of the cauda equina, of toxic origin, or secondary to the presence of a morbid growth; or it may be due to diabetes mellitus, alcohol, or syphilis.

TREATMENT.—This should be constitutional as well as local. Gout, rheumatism, syphilis, malaria—if inquiry show that any of these conditions possibly lies at the base of the disease—will need the treatment appropriate to each. In the presence of a gouty or rheumatic basis, the most common association, the diet should be spare in meat, with milk—all stimulants being as a rule avoided. Bicarbonate of potassium in effervescence, citrate of lithium, iodide of potassium, and colchicum will be among the drugs most likely to afford relief. If the gouty character be very pronounced, it will be well to give salicylate of sodium in ten- or twenty-grain doses, dissolved in half a tumbler of water, every three or four hours. The bowels should be freely acted upon with mercurial alteratives and Carlsbad salt. If syphilis be suspected, iodide of potassium or of sodium should be given, in doses of from ten to thirty grains three times a day or oftener.

Quinine, in doses of five grains, or arsenic may be employed if there be reason to believe that there is a malarial taint.

The recumbent position is very necessary in all cases of any severity; and, should the distress be very great indeed, it is a good plan to put the patient on a water-mattress. Or the affected limb may be preserved from movement by the application of a long splint, kept in position by a flannel bandage, changed daily. Sometimes the rapidly repeated application of very hot linseed-meal poultices will

give much relief. The application of an indiarubber bottle filled with very hot water rarely fails to soothe. On the other hand, cases of threatened severity have yielded to the application for several hours of bags of ice along the course of the nerve. Occasionally, if the pain and tenderness be very exquisite, and the patient's age and condition do not contra-indicate it, the application of a few leeches to the upper and back part of the thigh is useful. The synthetical compounds, phenazone in ten-grain doses, the same quantity of phenacetin with the addition of three-grain doses of caffeine, may be employed with advantage three or four times in the twenty-four hours. The hypodermic injection of morphine gives, of all remedies, the most speedy relief; but it is a hazardous remedy for the patient, who is very apt to acquire the morphine-habit. It is best to employ a solution of one grain in thirty minims, and to inject at first three minims twice in the twenty-four hours, if necessary. The dose may be increased by one minim at a time if it be found desirable; but it is rarely necessary, except in cases of malignant disease, to exceed eight minims of such a solution. The dose and frequency should be diminished as relief is obtained. The hypodermic injection of hydrochloride of cocaine is sometimes very useful. It should be performed at the seat of pain, and endeavour made to thrust the point of the syringe into the spot of greatest tenderness. The application may be repeated, if necessary, two or three times a day, in doses of gr. $\frac{1}{8}$ to gr. $\frac{1}{4}$. Care must be taken to avoid inducing the morphine- or cocaine-habit. The bowels should be kept thoroughly relieved. Flying blisters, not larger than a five-shilling piece, one following another as it heals, not on the same but on a closely adjoining part of the skin, may usually be applied with much advantage. Even in cases dependent upon malignant disease they will often give relief for a time. Spongiopiline wrung out of boiling water, and sprinkled with the compound mustard liniment, makes a good counter-irritant, and will sometimes take the place of blistering. Massage should only be employed in the absence of acute symptoms.

The continuous galvanic current is occasionally palliative. From twenty to forty cells may be employed; and while one rheophore is applied to the sacro-iliac synchondrosis, the other is dropped into a tub of warm salt water, in which the patient places his foot. The strength should be arrived at gradually, and the application continued for ten minutes at a time. Then, without removing the rheophores, the strength of the current must be gradually reduced to zero. Without this precaution a shock will be given, which is undesirable. The electrical application should not be employed during the very acute stage, but rather in cases of moderate severity, or where the most formidable suffering has subsided. It can be repeated at frequent intervals during the day. The current may be conveyed into a bath if preferred. One rheophore is allowed to fall into the bath, the other is held by the patient above the level of the water, which should be of a temperature of 95° F., and should contain some salt. In some cases, after acute symptoms have subsided, good has appeared to be done by enveloping the limb in a flannel bandage, over the folds of which sulphur is sprinkled. In other cases it is said that oil of turpentine taken internally has cured where other remedies have failed. In obstinate cases the sheath

of the nerve may be punctured in a few places with a sharp needle. See ACUPUNCTURE.

The baths of Buxton, Wiesbaden, Wildbad, Royat, and Gastein have been found useful in treating sciatica; and artificial hot-air or vapour-baths may be beneficial in some instances.

The sciatic nerve has been cut down upon and stretched with advantage in several cases of confirmed sciatica. The bloodless stretching of the nerve is, however, much to be preferred. This can be accomplished by flexing gradually at the hip-joint the extended lower limb of the patient, who lies upon his back, care being taken that the knee-joint is not flexed. See NERVES, Diseases of.

T. BUZZARD.

SCLEREMA NEONATORUM.—This name is applied to a condition of the skin and subcutaneous tissue, occurring congenitally or within a few days of birth, producing the hardening of the cutaneous tissues, which has given rise to a synonym of the disease—viz. the hidebound disease.

It may be present at birth or appear within the first ten days. The skin becomes of a pale white or waxy colour and has the feeling of hard leather. The uniform whiteness disappears in time and the tint becomes livid or even mottled. The subcutaneous tissue, as well as the skin, is also condensed, so that the integuments become bound down to the underlying structures. In this way a firm board-like texture is imparted to the integuments. The disease, as a rule, commences in the lower extremities, spreads upwards over the trunk, especially on the back, then gradually over the rest of the body, the face as a rule being the least affected. In all other parts the skin becomes quite board-like, so that the joints are fixed and the whole figure quite rigid. Even when the face is least affected, the cutaneous structures are so rigid as to prevent sucking or swallowing and the mouth cannot be opened. The nutrition of the infant rapidly fails, the respiration becomes very shallow and infrequent, the child is unable to cry and only produces a feeble moaning, and in a few days the vitality is so diminished that death occurs. Histological examination throws little light upon the nature of the disease. The epidermis is scarcely altered, though it may be thinner than usual. The subcutaneous tissue is firm and condensed, though no round-cell infiltration is present. The vessels of the cutis are small and appear to be contracted. The connective-tissue trabeculae, in the subcutaneous tissue, seem to be more than ordinarily well-marked. The causes of the disease are quite unknown, though it is stated that it is more apt to occur in children born under circumstances of poverty and defective hygiene. The prognosis seems to be inevitably fatal.

Œdema Neonatorum.—This is a form of firm subcutaneous œdema, affecting new-born infants. The disease commences within the first few days of life, generally in feeble children. The lower extremities are as a rule first affected. The disease advances by continuity or as separate patches over the trunk, especially affecting the back and buttocks. The swollen parts show firm œdema and pit as a rule with difficulty; they are red or livid in tint. The whole body may become affected in this way, or only small areas of disease may appear. In the more extensive cases rapid loss of strength is noted, the circulation is enfeebled, breathing becomes shallow, and death occurs from

vital depression or some other malady, such as diarrhoea, bronchial catarrh, &c.

Anatomical examination shows extensive changes in the affected skin. A large amount of serous effusion occurs in the connective tissues, and they seem much firmer than normal. The epithelium appears to undergo only slight change, but may be thinner than is usual. The internal organs have been found affected in various ways, but these alterations apparently have no distinct relationship to the disease. The liver has been found to be enlarged, the lungs catarrhal and congested, and nephritis has been found present.

The nature of the disease is obscure. It occurs in prematurely born children, in those who are feeble, or who are born under bad hygienic conditions. It seems, therefore, to have relationships to many debilitating causes.

The prognosis of the disease is not so hopeless as in sclerema neonatorum. In cases of œdema, if the whole surface is affected, the outlook is exceedingly serious. Many cases of localised œdema of the same type are seen, which gradually recover. As a rule, the course of the disease is longer than in cases of sclerema neonatorum.

TREATMENT.—Efforts should be made to retain the body-temperature by appropriate clothing and external warmth. The child may be wrapped in cotton-wool in a warm room, or placed in an appropriate incubator. As a rule, on account of the face being affected, the child is unable to suck, and must be then fed artificially, by passing a tube into the pharynx. Milk in some form is obviously the only diet permissible. Much advantage has been obtained by the use of gentle massage of the affected parts, especially when the disease is localised.

JAMES GALLOWAY.

SCLERODERMIA (*σκληρός*, hard; and *δέρμα*, the skin).—**SYNON.** : Addison's Keloid; Morphea.

DEFINITION.—A chronic disease of the skin, circumscribed or diffuse, in which an excess of fibrous tissue leads to hardness, change of colour, and by contraction to stiffness and immobility.

ÆTIOLOGY.—Scleroderma is a rare disease of the skin, which occurs at all periods of life, but more frequently in young adults and in middle age. It is more frequent in women than in men. Little is known as to its causation; but rheumatism, especially of the joints, has been known to precede the attacks, and it has sometimes followed exposure to wet and cold. It attacks persons otherwise in good health. The circumscribed form sometimes follows the course of cutaneous nerves, and for this and other reasons it is regarded by some authors as essentially a tropho-neurosis. So far, however, the correctness of this view cannot be considered as having been definitely established. In some cases the circumscribed form has been referred to irritation caused by blows, blisters, pressure, and other causes.

ANATOMICAL CHARACTERS.—The essential structural changes consist in an increased formation of connective tissue, the new elements following especially the lines of the vessels. The number of elastic fibres appears increased in certain parts of the skin. The formation of new fibrous tissue takes place not only in the corium, but in the panniculus adiposus, and extends to the deep fascia and periosteum. In its overgrowth the fat disappears, and the smooth muscular fibres appear to be hypertrophied.

The papillary body is rendered more dense than usual by bands of connective tissue, and there is an increase of pigment both in it and in the rete. Otherwise the epidermis is unaltered. In the early stage the effusion leads to hypertrophy of the cutis, but later the contraction of the fibrous tissue causes atrophy of the integument and narrowing of the blood-vessels. At first the sebaceous and sweat-glands are unchanged, but they are afterwards atrophied. Sometimes there appears to be a dilatation of the sweat-glands in the early stage. In the extreme atrophic stage of diffuse sclerodermia the compression leads to more or less disorganisation of ligamentous tissues.

DESCRIPTION.—Sclerodermia is found in two well-marked forms—*diffuse* and *circumscribed*, which in their typical development differ so much from each other in appearance that they were formerly considered to be distinct diseases, the circumscribed form being known and usually described as *morphea*. Transition-forms are, however, sufficiently common to establish the nosological identity of the two varieties of the affection.

Circumscribed sclerodermia.—A developed patch of circumscribed sclerodermia is usually characterised by a rounded area of white or yellowish-white skin, which in some cases looks like smooth ivory. Around this patch there is a yellowish or brownish pigmentation. The white surface is usually firm to the touch, brawny, and difficult to pinch between the fingers. The sensibility is unimpaired. The earliest stage in the development of such an area is characterised by hyperemia, small dilated blood-vessels shining through the surface. The disease may begin in one or more such isolated patches, which, as they become circumscribed, are surrounded by a well-marked lilac border of minute blood-vessels. Such a patch may remain for months or years without much change, or it may undergo involution, which sometimes takes place quickly, leaving the skin healthy; or, on the other hand, it may become atrophic, the skin becoming thin, parchment-like and cicatricial.

These patches occur in various parts of the body, but most frequently on the neck, face, chest, trunk, arms, and thighs. They are unsymmetrical. There is a sufficient number of cases on record in which the changes in the cutis have followed the track of certain nerves, which would indicate some relation to nerve-distribution. The affected skin does not sweat. There are usually no subjective symptoms, but there may be itching, or tingling, occasionally even pain. Circumscribed sclerodermia sometimes occurs in the form of bands, which are usually depressed below the surface and more or less adherent to underlying parts, and sometimes extend for a considerable length.

Diffuse sclerodermia.—This occurs on different parts of the body, but more usually in its upper half. It may be limited to certain parts, the skin between them remaining normal, or it may be spread over large areas of the integument, such as the back, abdomen, limbs and face. It may develop after a short period of malaise, but as a rule the process is at the beginning not observed by the patient, his attention being first called to it by stiffness of the skin; or pigmentation may be early observed. Stiffness is usually first felt about the neck, chest, shoulders or arms, and spreads with more or less rapidity towards the limbs, the border being usually ill-defined, although to some extent

perceptible to the touch. Doughy infiltration or erythema may precede the induration. As the skin becomes hard and stiff, mobility is affected, the joints becoming fixed and the face immobile. The patient cannot open his mouth widely, and the affected surface of the body has been compared to that of a frozen corpse, without, however, being cold. The skin does not pit, and cannot be pinched up. The patient is usually hidebound. The respiration is impaired, the breasts flattened, the limbs and fingers more or less flexed. The disease may even extend to the mucous membranes. The contraction of the skin leads to the disappearance of wrinkles, old persons looking younger than their years. The surface is generally smooth and shining, but sometimes dry and desquamating, the skin being pale, whitish and waxy. The disease may reach its full extent in a period of weeks or months.

The temperature of the affected skin is on the whole normal, sometimes being slightly above and sometimes below the average. Pressure is felt, and the tactile sensibility is usually unaffected, but sometimes weakened. Secretion of sweat may be diminished. The sebaceous secretion is usually normal. The nutrition of the affected skin being impaired, it is liable to inflammation and ulceration from the ordinary sources of irritation. The limbs, from compression of the continually contracting skin, gradually become smaller. The palms and soles are rarely affected.

The course of the disease varies considerably. In the early stages a spontaneous cure may occur, involution sometimes taking place at one part while new development is showing itself at another. When shrinking and atrophy have proceeded to an extreme extent life becomes threatened. The general health in the earlier stages of the disease does not seem to be notably affected; but as atrophy and shrinking proceed, the patient falls into a condition of marasmus, and death occurs from intercurrent complications of various kinds. Kaposi refers to a case of Strassmann's, which had lasted thirty-one years without the health being materially affected.

DIAGNOSIS.—Sclerodermia is not likely to be confounded with other diseases characterised by hypertrophy and œdema. The tension, rigidity, hardness, and shrinking of the diffuse form are distinctive; in the circumscribed form the pigmented and hyperæmic zone surrounding the waxy patches distinguishes it from leprosy and vitiligo. In anæsthetic leprosy, anæsthesia is characteristic. In atrophic conditions there is a history of a previous hypertrophic stage.

PROGNOSIS.—Recovery may take place so long as the atrophic stage has not set in, improvement showing itself within a period of weeks or years. In the atrophic stage the prognosis is unfavourable, death being due to complications of various kinds.

TREATMENT.—Tonics, such as iron, quinine, vegetable bitters, cod-liver oil, and arsenic, are believed to assist a tendency to recovery when it is present. Baths, vapour-baths, hot packing, change of air, emollients, such as simple ointments, glycerine, or vaseline, and massage, are recommended. The continuous current applied to the affected skin and sympathetic nerve is believed by some authorities to be useful. It is recognised that iodine and mercurials have no value. Warm clothing and general protection against cold are indispensable.

G. THIN.

SCLEROSIS (*σκληρός*, hard).—SYNON.: Fr. *Sclérose*; Ger. *Sclerosis*.—See FIBROSIS; and SPINAL CORD, Diseases of.

SCLEROSTOMA (*σκληρός*, hard; and *στόμα*, a mouth).—A synonym for *Ankylostoma duodenale*. See ENTOZOA.

SCLEROTIC, Diseases of.—See EYE, AND ITS APPENDAGES, Diseases of.

SCORBUTUS.—A synonym for scurvy. See SCURVY.

SCRIVENER'S PALSY.—A synonym for writer's cramp. See WRITER'S CRAMP.

SCROFULA (*scrofa*, a sow).—A term applied to a supposed hereditary tendency to slowly progressive chronic inflammations, and caseation, especially of lymphatic glands. The large majority of such cases are now known to be instances of chronic local tuberculosis, and the term is rapidly falling into disuse. See TUBERCULOSIS.

SCURF.—A popular name for the bran-like exfoliation which forms at the roots of the hair. It is composed of the normal desquamation of the epidermis of the scalp, with the addition of the epithelial exuviae thrown off by the hair-follicles. See PITYRIASIS.

SCURVY.—SYNON.: *Scorbutus*; Fr. *Scorbut*; Ger. *Scharbock*.

DEFINITION.—Scurvy is a disease characterised clinically by intense general debility; sponginess and swelling of the gums; ecchymoses, closely resembling bruises, about the thighs and legs; a brawny hardness about the flexures of the larger joints, and sometimes a contraction of the muscles of the calves; pearly conjunctivæ; and a sallow aspect somewhat akin to mild jaundice.

From a pathological point of view the disease is characterised by effusion of a fibrinous material in the tissues of the gums, between the striæ of the muscles of the thighs, legs, and sometimes (but comparatively seldom) of the arms, and also between the periosteum and the bones of the extremities, and occasionally of the ribs; ecchymoses sometimes found about the thoracic and abdominal aortæ and the alimentary canal; and a generally blanched condition of all the tissues.

ÆTIOLOGY.—At the present time the interest of this disease is largely historical, improved conditions both on sea and land having abolished the extensive and fatal outbreaks which were familiar to physicians of a former age; but experience has shown that when war, famine, or shipwreck reproduce the conditions which gave rise to it, it may be expected to reappear, with all its former virulence. It has also from the earliest times been a chief foe to sailors; and until the beginning of the seventeenth century it constituted a formidable item in the mortality-list of the navy in this as in other countries. Since, however, the prophylactic properties of a vegetable diet have been understood, scurvy has—except under very unusual and always preventable conditions—ceased to assume formidable proportions either ashore or afloat. Cases of the disease are still seen occasionally in hospitals at seaports, usually associated with some other disease, as dysentery, ague, &c.; but in some instances clearly caused by carelessness, either on the part of the

captain in serving out, or on the part of the crew in taking, the lime-juice provided. In recent years it has been recognised that young children brought up on preserved or artificially prepared foods are apt to suffer from scurvy, and this liability seems likely to increase, owing to the number of patented foods which are continually being placed on the market, and used by the well-to-do classes as substitutes for mother's milk.

PATHOLOGY AND ANATOMICAL CHARACTERS.—We are still in ignorance of the precise nature of the alterations of the blood and tissues which precede and accompany the development of the disease. It has, however, been shown that there is a considerable diminution of the red blood-corpuscles, an increase in the amount of fibrin and albumen, and no decrease in the amount of potassium-salts. Ralfe, from observations founded on the effect which the withdrawal, for a considerable period, of all fresh succulent vegetables and fruits had on the urine of healthy persons, and from analyses of urine from patients suffering from the disease, concluded that the 'primary alterations in scurvy depend on a general alteration between the various acids, inorganic as well as organic, and the bases found in the blood, by which (a) the neutral salts, such as the chlorides, are either increased relatively at the expense of the alkaline salts; or (b) these alkaline salts are absolutely decreased. This condition produces diminution of the normal alkalinity of the blood; and he suggests that this diminution produces the same results in scurvy-patients as happens in animals when attempts are made to reduce the alkalinity of the body (either by injecting acids into the blood or feeding with acid salts), namely, dissolution of the blood-corpuscles, ecchymoses and blood-stains on mucous surfaces, and fatty degeneration of the muscles of the heart, the muscles generally, and the secreting cells of the liver and kidney.' This and other chemical explanations are inconsistent with the important fact that the antiscorbutic properties of foods are destroyed by desiccation and overheating, processes which do not affect the proportions of the acids and bases they contain.

The most marked morbid changes of scurvy are the œdematous, spongy, and occasionally ulcerated gums; the bruise-like condition of the legs; and the brawny hardness, confined usually to the gastrocnemii and hamstring muscles. On cutting these across, tough fibrinous effusions are found packed between the muscular striæ, giving the cut surface a streaky appearance. If the anterior surface of the tibia be examined, the same kind of effusion will be often found between the periosteum and the bone. It would appear that the effusion is due, not to the degenerated condition of the vessels, but to a chemical alteration of the blood. True hæmorrhagic effusions are sometimes found beneath the periosteum, or between the epiphyses and diaphyses of the larger joints, especially when scurvy has proved fatal in children.

In severe cases the ribs will sometimes be found detached from the cartilages, and old fractures occasionally become disunited. Beyond a general anæmic condition, and occasional ecchymotic spots about the pleura and pericardium, the contents of the thorax present no special appearances. Lesions due to complications, such as dysentery, malaria and syphilis, will frequently be found. The body is not always badly nourished, and the cheeks are

usually puffy on account of the swollen gums; but local or general dropsy is seldom present.

SYMPTOMS.—The most striking features of scurvy are the spongy condition of the gums and the presence of brawny painful swellings in the hams. The complexion is of a sallow, dull, leaden hue, resembling that of a patient who has been for a long time subject to attacks of some form of remittent or intermittent fever, or that of a person recovering from jaundice; pearly-white conjunctive; puffy and sometimes bloated cheeks; spongy gums, bluish-red in colour, swollen sometimes to such an extent as to hide the teeth both in front and behind, and tending to bleed; teeth more or less loose, some already lost; tongue clean and pale; no special characteristic about trunk and upper limbs (though the latter are now and then slightly ecchymosed); shortness of breath, but no other chest-complication; no abdominal tenderness or anything abnormal as to the functions of the abdominal organs; thighs and legs usually presenting a more or less bruised appearance, particularly just above and below the knees; and brawny indurations of the hams and calves of the legs, often painful and tender. The effusions previously described may be so dense and abundant as to fix the legs in a semi-flexed position. Node-like swellings are also often observed over the tibia, owing to effusions between the periosteum and the bone. The swelling of the gums is specially noticeable round decayed teeth, and old injuries to the limbs seem to be the seat of the characteristic effusions. There are also usually a large number of spots and patches, very much like those of purpura, scattered indifferently about the lower limbs. There is sometimes considerable œdema about the ankles; but, in uncomplicated scurvy, pitting on pressure anywhere is the exception rather than the rule. The bowels are more or less constipated, the appetite is good, and there is no thirst. The breath has a peculiar offensive odour, and this may be aggravated by ulceration or sloughing of the gums, or necrosis of the jaw. General debility varies in degree, but may be excessive, with weak voice, and some tendency to fainting, if the patient is put or kept in a sitting position. He feels more or less general aching, and a sensation of contusion in the legs. The skin is dry and harsh, and desquamates over the legs. Cardiac and pulmonary sounds are normal. The urine is free from albumen, of normal specific gravity, with abundant chlorides. Urea and phosphates are said to be deficient.

In children the disease generally begins between the ages of six and eighteen months. In them the most prominent symptom is extreme tenderness in the legs, so that the patient lies perfectly still, and shrinks at the slightest touch. The gums are affected as in adults if the teeth have appeared or are pushing, and hemorrhages in various parts of the body are not uncommon.

COMPLICATIONS AND SEQUELÆ.—Simple scurvy is now rarely seen inland, except among the extreme poor who may be unable to purchase vegetables, and who live merely on tea and bread. In children, however, it appears to be more common among the middle classes, being due to the extensive use of patent or predigested foods, which are beyond the reach of the poorer classes. Nor is it very often seen afloat. It still, however, complicates to a considerable extent diseases or accidents that occur at sea, and so prolongs convalescence almost indefinitely. A sailor, for example, goes

out from England to Calcutta, and shortly after arrival in that port is attacked with dysentery or intermittent fever, fractures a limb, or becomes syphilitic. He remains in India a very short time, ships in a convalescent and enfeebled condition, lies up before the ship has been at sea many days, and probably does little or no work during the entire passage. The berth that he occupies constantly (and with very little change of clothing) is probably wet, his food scanty and unvaried, and his lime-juice or other antiscorbutic (as he cannot go to fetch it) served out irregularly, or perhaps refused when given. Under such circumstances, scurvy soon begins to 'colour' the original disease. The intestinal canal in cases of dysentery, the spleen in cases of ague, buboes, and chancres in syphilis, are all attacked, so to speak, scorbutically. Wounds, scratches, ulcers, or any other breaches of surface will not heal, and fractures sometimes become disunited; so that, as a consequence, the recovery of the patient after his arrival is deferred (solely on account of the existence of this scorbutic condition) for several weeks or months. In fact, all processes of repair, internally and externally, appear to be arrested, and no advance is made until the scorbutic symptoms have entirely disappeared. Nyctalopia is sometimes associated with scurvy, and it may be considered that night-blindness is induced by scorbutic conditions, inasmuch as this affection has decreased *pari passu* as scurvy has diminished in the British Mercantile Marine, and is now seldom complained of by sailors. In bad cases, hæmorrhage may take place from mucous surfaces. Nausea and vomiting may also occur.

The sequelæ of uncomplicated scurvy are, practically speaking, *nil*, for the patient, when properly treated, makes a rapid and complete recovery, leaving no trace of the disease behind. There appears, however, to be little doubt that one attack renders the patient less able to resist successfully future onsets of the disease, if placed under the same predisposing conditions. Several instances are recorded of old sailors, who have been the subjects of two or three attacks; but these have been generally complicated with some other disorder, delirium tremens being occasionally superadded.

DIAGNOSIS.—The diagnosis of scurvy cannot be difficult if the symptoms described above exist, and a dietetic history is carefully made out. This important item of information being established, the spongy gums, and the bruise-like condition of the lower limbs (this latter condition not being connected with any history of accident or injury), together with great general debility, should be sufficient to determine the nature of the disease. For even in mild cases the condition of the gums is quite unlike that produced by mercury. Moreover, the mercurial fœtor is absent, but an offensive earthy odour exists. Nor has the blue margin seen in the gums in cases of lead-poisoning any resemblance to the scorbutic condition. Scurvy might be occasionally confounded with purpura, as in some cases hæmorrhagic spots only exist about the legs, with no ecchymoses or hardness round the calf and hamstring muscles. But the condition of the mouth, the absence of severe cachexia, and, as Niemeyer remarks, the comparative absence of epistaxis, hæmatemesis, hæmatoma, and bloody evacuations from the bowels, will at once settle the diagnosis.

In children scurvy is not likely to be overlooked

if the possibility of its existence is borne in mind. Some doubt may arise whether the symptoms are not due solely to rickets, which is often present as a complication. It may also be confounded with rheumatism, paralysis, or joint-disease; or if hæmaturia is present with Bright's disease. The peculiar swollen and painful state of the legs, the spongy gums, and still more the effects of treatment, will serve to distinguish the disease.

PROGNOSIS.—Scurvy existing apart from other maladies is not a fatal disease. The patient may be seen in a state of excessive prostration, with feeble pulse, whispering voice, and a tendency to syncope; but a few days' rest, under favourable conditions, and proper treatment, produce a marvellous change, which results in a steady and very satisfactory convalescence. But before a prognosis is given, care should be taken to ascertain that the scurvy does not cover any other disease. Dysentery, syphilis, and the various forms of intermittent fever are undoubtedly its worst complications, and either of these maladies will, even under favourable circumstances, prolong convalescence considerably. The duration of the disease is limited only by the causes that produce it, for as long as the scorbutic diet and other predisposing conditions exist, so long will the disease retain the mastery, and progressively increase in severity.

TREATMENT.—If the patient, when first brought under notice, be so ill as to be unable to walk or stand, great care should be taken that the recumbent position is adopted and maintained. Many severe cases of scurvy have been lost by the neglect of this apparently simple precaution. The patient, in the absence of the nurse, sits up in bed, and has a sudden attack of syncope, from which he never recovers. Having regard to this, let the patient be undressed carefully, and washed (without a bath), any wounds or abrasions being covered with some simple antiseptic dressing. The direct treatment of the disease is almost purely dietetic, starting upon the principle that want of fresh vegetable diet has been the exciting cause of the illness. So the diet should consist largely of mashed potatoes; green vegetables (the *Cruciferae* being perhaps the best); oranges, pears, apples; and, as a convenient antiscorbutic, lime- or lemon-juice at the rate of from three to four ounces daily, mixed with about eight times its bulk of water, sweetened to taste, and used as a drink. Solid animal food should be given at least once a day, and in liberal quantity, as soon as it can be properly masticated. We begin in bad cases with milk, eggs, fish, and minced meat—in fact, any and all varieties of nutritious animal food, in conjunction with the vegetable diet; for the appetite is usually good, and the digestive powers almost unimpaired. If great prostration exist, alcohol, in small and frequent doses, must of course be given; but, as a general rule, very little is required. Mal-liquors are undoubtedly antiscorbutic, and a pint of ale or porter daily may be permitted if no dysenteric complication exist. Milk is also to a certain extent antiscorbutic, and should be given freely. As regards medicinal treatment, little or nothing need be done. All active treatment, general or local, is almost useless. The administration of mercury to scorbutic patients (through errors of diagnosis) did, in former years, an enormous amount of mischief, and, even in the presence of chest-complications, all counter-irritants to the skin must be avoided. Chlorate of potassium, in the form of a mouth-

wash, or given internally, probably assists to cleanse and purify the gums and mouth; and if old ulcers or open sores exist upon any part of the body, lint, wetted with weak lime-juice, is said to promote a healthy surface. But if there be any complication, no processes of elimination or repair will advance satisfactorily until the scorbutic symptoms disappear. If no grave disorder beyond the scurvy exist, recovery is very rapid, and few diseases are so eminently satisfactory to treat. The gum-swellings recede, and the ecchymoses on the legs begin to disappear after two or three days of treatment; and the brawny tenderness of the muscles of the lower limbs diminishes daily, the fibrinous effusions causing it being steadily and quickly absorbed. Dysentery is the most common complication of scurvy, and is usually tedious and troublesome. A fair trial should be given to the treatment above recommended, excluding malt-liquors, and substituting a small allowance of brandy, and as a rule the dysentery and scurvy will disappear together. In children fresh milk that has not been sophisticated in any way should as far as possible be employed, but as a rule is not sufficient by itself. One of the most useful remedies in these cases is potato, which should be well steamed and reduced to a light floury powder and beaten up with boiled milk until it is of the consistence of cream. Vegetable juices may also be given dissolved in broth.

The antiscorbutic treatment proper to combat the advent of this disease is sufficiently indicated in the above remarks, for it will be plainly seen that scurvy is due to the absence of certain necessary ingredients in diet. When these ingredients cannot be given in the usual form, the most convenient substitutes are lime-juice and lemon-juice, and the great mass of evidence, collected during the last fifty years, goes to prove that these substances contain, in natural combination, the best and most convenient prophylactic elements against scurvy. Their use in the Royal Navy has, since the close of the last century, been chiefly instrumental in driving the disease out of the Service; and legislative enactments passed in 1867, whereby a proper and genuine supply of juice was secured to all British sailors, have resulted in the decrease of scurvy in our own Mercantile Marine by more than 80 per cent.

CHARLES H. RALFE.

THOMAS R. BRADSHAW.

SCYBALA (σκύβαλον, dung).—Fæces in the form of hard rounded lumps, whether discharged or retained in the intestine. See *STOOLS*.

SEA-AIR; SEA-BATHS.—The physiological and therapeutical effects of sea-bathing cannot be separated from those of sea-air; for it is impossible to take sea-baths without being under the influence of sea-air; and the stay at the seaside alone, without sea-bathing, produces on many constitutions all the effects which are usually ascribed to sea-bathing. Residence at the seaside, that is, the influence of sea-air, is to be regarded as a special kind of climatic treatment, while the action of the sea-bath is analogous to the stimulating forms of the cold-water treatment.

As the sea-air and the sea-bath owe part of their properties to the constitution of sea-water, it will be well to begin with the latter, then to consider the characters and influences of the sea-air and the

sea-bath, and add some notes on seaside watering-places.

Sea-water.—*Temperature.*—The sea-water is of more equable temperature than the surrounding air. It is, as a rule, warmer than the atmosphere in winter, and cooler in summer; although on chilly days in summer, especially after a series of hot ones, the temperature of the sea-water is often higher than that of the air. The variations of the temperature of the sea-water from night to day, and from one day to another, are much less than those of the air. It would, however, be erroneous to assume, as is sometimes done, that the temperature of the sea-water near the shore is the same at different times of the day. The writer has often measured it at the Riviera, and the south coast of England, and has repeatedly found it on calm and sunny days at one P.M. and two P.M., from 5° to 7° F. higher than on the same days at seven or eight A.M. As to the different seasons, the sea-water reaches its highest temperature in summer much later than the air; and as it loses its heat less rapidly than the latter, it is mostly warmer in autumn and winter than the surrounding air, and gives off warmth to the latter. During the sea-bathing season, namely, from the end of May to the beginning of October, the temperature of the sea-water at the coasts of England, the north of France, Belgium, Holland, and Germany, varies in general from about 56° to 72° F., while in the Bay of Biscay and in the Mediterranean it is considerably higher.

Constituents.—Sea-water holds in solution a large amount of salts, varying somewhat in different localities, and slightly even in the same place at different times. The Mediterranean is richest, with about 2¾ to 3½ per cent.; while the water at the coasts of the British Channel and German Ocean varies from 2¼ to 3¼ per cent. The water of the Baltic, owing to the large number of streams which enter it, is much less salt, containing only about ½ per cent. Five-sixths of all the salts are chlorides of sodium and magnesium, while the remainder consist of the sulphates and carbonates of calcium, magnesium, and potassium.

Sea-air.—The sea-air, and the air at the sea-shore, are considerably influenced by the constant evaporation taking place from the sea, and also by the temperature of the sea-water. Owing to these circumstances, the sea-air contains in general more moisture, relative as well as absolute; and is more equable in temperature, the summer being less hot, and the winter less cold, at the seaside than at inland places in the same latitude; the day also may be regarded as less warm in summer, the night as less cold in winter. A very important fact is the comparative purity of the sea-air from organic admixture and inorganic dust, while the occasional presence of a greater or smaller amount of saline particles cannot be regarded as a disadvantage. The amount of ozone is greater; that of carbonic acid smaller. The variations of the barometer are greater but more regular in their occurrence, and this possibly exercises a beneficial influence on the functions of life. Nor is the fact to be overlooked that the air at the sea-shore is mostly in greater agitation than the inland air; and by this circumstance is probably to be explained the experience of Benecke that the same body of hot water loses its heat more rapidly at the sea-shore than at various elevations in Switzerland, varying from 3,000 to 6,000 feet above sea-level—an experience

from which we may infer that living bodies likewise give off more heat at the sea-shore than in elevated inland regions. The physiological effects of sea-air may be designated as 'powerful stimulation of the change of substance, both retrogressive and formative, expressed in a striking increase of urea, and decrease of uric acid and phosphoric acid in the urine, in the greatly increased requirements of food, and in the rapid and considerable increase of the weight of the body.' A certain power of responding to the increased stimulus of the sea-air is, however, required of the constitution; for the increased tissue-change necessitates an increase in the ingestion of food, and in the processes of excretion of the products of retrogressive tissue-change. If the digestive and assimilative organs be unable to satisfy the former demand, various digestive disturbances arise, the appetite fails, and emaciation is often the consequence. In many of these conditions greater benefit is derived from mountain health-resorts, where the demands made on the constitution are less great, and where less food is required. If the excretory functions be imperfect, as is the case in so-called 'bilious' individuals, and in some undefined gouty tendencies, headaches, giddiness, constipation, or other symptoms usually called 'biliousness,' make their appearance, and sometimes render the removal from the sea-shore necessary, though the use of aperient remedies, reduction in the amount of food and especially of stimulants, and active exercise at some distance from the sea, often suffice to correct this defective elimination and its consequences. In many cases of this kind, however, courses of mineral waters, especially the alkaline, saline, or common-salt springs, ought to precede the stay at the seaside. See MINERAL WATERS.

Sea-baths.—The sea-bath may be regarded as a powerfully stimulating cold-water bath, modified in its action by the saline ingredients; by the admixture of mechanical particles, organic as well as inorganic; by the varying degree of motion through the waves; and by the alternation in the exposure of a part of the body to the waves and to the air. We have already discussed the temperature of the sea-water, and the saline ingredients; but the temperature of the surrounding air, and the degree of motion in the air, also exercise a modifying influence on the effects of the sea-bath. The motion of the water varies constantly, according to the size and force of the waves, and the effect of the bath to a great degree depends on this point. When the waves are in any degree powerful, the upper part of the body is exposed to the coming, the lower to the receding wave, and the cutaneous nerves are not only influenced by the temperature, but also by the force of the water, and by the sand and other substances mixed with it. In a quiet sea these influences are considerably lessened. The alternation of exposure to the water and the air, likewise occasioned by the waves, is peculiar to the sea-bath, and is another source of constantly changing impressions on the cutaneous nerves.

BATHING SEASON.—The season for sea-bathing varies according to the climate of the locality. Thus it extends on the Mediterranean shores from May to October and even November; on the shores of the English Channel and German Ocean from June to September and the beginning of October. The time of the day for sea-bathing must depend on the individual, on the weather, and on the tide. Delicate

persons ought not to bathe with a perfectly empty stomach; but also never after a full meal. The duration of each bath is to be regulated according to the constitution of the bather, the force of the waves, and the temperature of the water. Weakly persons ought not to remain in the water over five minutes, but immersion for one or two minutes is in many such cases all that is useful or permissible; while stronger individuals may remain from five to ten minutes. The bather, we may say in general terms, should leave the water as soon as the reaction manifests itself.

In many cases, the warm sea-water bath may be recommended with advantage, when the cold sea-bath is forbidden. Indeed, courses of bathing in warm sea-water are not sufficiently used in a systematic way, though the medical practitioner possesses in them a gentle, manageable, and efficacious means of treatment during winter as well as during summer. They are in their action analogous to warm common-salt baths (*see* BATHS; and MINERAL WATERS). The tepid swimming-bath of sea-water we may regard as intermediate between the warm bath and the bath in the open sea, and likewise as very useful in appropriate cases. With due care it can be employed also in winter. It offers the advantage of the combination of one of the most perfect modes of muscular exercise, with the exposure of the skin to the influences of the sea-water bath.

The physiological effects of the sea-baths are similar to those of the sea-air. Abstraction of heat and stimulation of the cutaneous nerves lead to increased tissue-change, retrogressive as well as productive. Increased appetite and increased weight of body are usually observed in those who are benefited by sea-baths; while loss of appetite, headache, digestive disturbances, and loss of weight are often observed in those who are unable to bear the shock, or the increased demand on the body, or who remain too long in the bath, or take it too frequently.

CASES NOT SUITED FOR SEA-BATHING.—Persons affected with diseases of the heart, or of the blood-vessels and lungs, with angina pectoris, with epilepsy, with organic diseases of the nervous system, with fainting fits, with enlargement of the liver, or with other organic diseases of the abdominal viscera, ought to avoid bathing in the open sea, which may produce most injurious effects, such as violent palpitation and dyspnoea extending over many months, sleeplessness, total loss of appetite, and great emaciation. Old persons, and persons with feeble circulation, whether from age or otherwise, ought to avoid bathing in the open sea, excepting on warm days, and with a very quiet sea.

CASES TO BE BENEFITED BY SEA-BATHING AND SEA-AIR.—Sea-bathing is useful in many conditions connected with weakness or atony of the skin, such as tendency to profuse perspiration, or to taking cold at every change of temperature, or exposure to wind or draught.

In scrofulous complaints, long-continued residence at the seaside promises more than other climatic agents; but, as we have to deal with constitutional defects, and as our aim must be to alter the constitution, two, three, or even more years are often required. In many cases, judicious courses of sea-bathing, the use of warm sea-water baths, and sponging with sea-water, assist the climatic element of seaside residence. Education at schools situated

at the seaside offers, in scrofulous children, the greatest advantages.

In muscular rheumatism, the moderate use of the sea-bath combined with sea-air is useful. In more recent rheumatic joint-affections the sea-bath is mostly injurious, while the more gentle action of the sea-air, combined with the use of warm sea-water in local and general baths, is frequently beneficial. Persons affected with so-called nervous rheumatism—a term which is applied sometimes to hysterical cases, sometimes to spinal irritation, and also to rheumatism combined with nervous weakness—often derive benefit from the gentle use of the sea-bath, and still more from the sea-air.

In some functional diseases of the nervous system, the sea-bath forms an excellent remedy, if it be adapted to the individual case; for instance, in hysterical paralysis and other forms of hysteria, in the milder forms of diphtheritic paralysis, and in nervous dyspepsia. It must, however, be borne in mind that many persons, with a tendency to neuralgia, nervous asthma, hysterical convulsions, and other forms of hysteria, are unable to stand prolonged residence at the sea, especially at the Riviera. In such cases, mountain climates are generally more advantageous during summer and autumn. In many forms of anæmia, when it does not depend on organic disease of the heart and blood-vessels or other viscera, but on direct loss of blood or its constituents, on confinement, grief, and imperfect food, on slow and imperfect development, sea-air exercises a good effect. Hence the benefit obtained in many cases of amenorrhœa, chlorosis, and allied complaints, if the tendency to constipation is sufficiently combated. Often, however, the demands made by the sea-air on the constitution are too great, and the invalids lose weight; whereas they gain on mountains of moderate elevation.

In chronic pneumonia, in the remains of pleuritic effusion, and in phthisis, the sea-air, by its purity and its more equable temperature, is useful; but as wind is in most cases to be avoided, sheltered localities are essential. Sea-bathing is in this class of cases hazardous. The beneficial effects in whooping cough, when the first stage is over, are well-known. Regarding asthma, nothing can be said with certainty; some cases of nervous asthma are benefited at the seaside, while a large percentage are aggravated; on the whole, the writer's experience is more in favour of elevated regions than of the seaside. Whenever the effect is not yet known, the recommendation of seaside residence or mountain-air must be regarded as a trial; but in the majority of young persons affected with asthma, mountain climates are preferable. The advantage to be obtained in tendency to catarrh we have already mentioned.

In addition to the conditions named, there are many which cannot be designated by the name of any disease; but which are only states of weakness, manifesting themselves in various ways, as inability to sustain mental or bodily efforts, tendency to abortions, to leucorrhœa without any disease, &c. In such states of weakness the stimulating effect of the sea-air, combined with the grand aspect of the sea, are mostly found eminently useful.

SEASIDE WATERING-PLACES.—England is remarkably well provided with seaside places, and the different localities offer considerable variety with regard to climate. The east coast, which may be

designated as drier and more bracing, is especially to be recommended from the middle of June to the middle of October. The principal places on this coast are, beginning with the north, Berwick-on-Tweed, Tynemouth, Redcar, Saltburn-by-the-Sea, Whitby, Scarborough, Filey, Bridlington, Hunstanton, Cromer, Yarmouth, Lowestoft, Aldborough, Felixstowe, Dovercourt, Walton-on-the-Naze, Southend, Margate, Broadstairs, Ramsgate, Deal, and Dover. On the south-eastern and southern coast, which may be regarded as intermediate between the eastern and the south-western coast, we have Folkestone, Sandgate, Hastings with St. Leonards-on-Sea, Eastbourne, Seaford, Brighton, Worthing, Littlehampton, Bognor, the Isle of Wight, Bournemouth, and the Channel Islands. These places differ considerably with respect to the soil on which they lie; the position—close to the sea or on a cliff; the aspect; and the configuration of the locality itself, and the surrounding country. Even different parts of the same place offer different advantages. Thus the lower part of Folkestone, near the lower Sandgate road, is sheltered from the north by the cliff, while the houses on the cliff itself are more or less freely exposed to the winds from all quarters, and therefore preferable during the summer months. Hastings with St. Leonards is remarkably sheltered from the north, north-west, and to some degree from the north-east winds, and is through this, and through the influence of the sea, some degrees warmer during the late autumn and the early winter months—we may say till February—than closely adjacent but less sheltered places. In the Isle of Wight, the Undercliff, with Ventnor and Bonchurch, is sheltered by the hills from north and north-east winds, like Hastings, and more so; and has during winter a more equable and a higher temperature than other parts of the island. The Undercliff is therefore more adapted for climatic treatment during the colder part of the year; while Sandown, Shanklin, Cowes, Ryde, Alum Bay, and Freshwater are more suited for sea-bathing and climatic purposes during the warmer months. Bournemouth is sheltered as well by the configuration of the hills as by the pine-woods, which serve as a protection from violent winds. On the south-western coast, which may be regarded as somewhat moister and more sedative, Swanage, Weymouth, Sidmouth, Budleigh Salterton, Dawlish, Torquay, Teignmouth, Falmouth, Penzance, St. Ives, and Newquay are the principal sea-bathing places. On the North Devon coast, we may name Clovelly, Lynmouth, Ilfracombe, Westward Ho, and Minehead; on the Bristol Channel, Weston-super-Mare, Portishead and Clevedon; on the Welsh coast, Tenby, Aberystwith, Penmaenmawr, Llandudno, Rhyl; and in Lancashire, Westmoreland, and Cumberland, Grange, sheltered by configuration, Southport, Blackpool, Fleetwood, St. Bees, and Silloth. Important by its island climates is the Isle of Man.

Scotland likewise offers abundant localities for sea-bathing, the most frequented of which are Nairn on the east coast, Rothesay in Bute, Ardsrassan near the Firth of Clyde, and the Isle of Arran in the west.

Ireland is even richer, with Bray and Kingstown, near Dublin; Duncannon, Tramore, and Dunmore on the south coast; Rostrevor and Portrush on the north-east; Bundoran in the north-west; Kilkee in the south-west; and Queenstown, a sheltered and warm, but moist, climatic health-

resort in the south; where are also Youghal and Ballycotton.

On the north coast of France, Calais, Boulogne, Berk-sur-Mer, St. Valéry, Tréport, Dieppe, Etretat, Fécamp, Havre, Trouville, Deauville, Villers-sur-Mer, and Dinard are the most favourite resorts; on the south-west, Arcachon and Biarritz; and on the south Marseilles, Hyères, St. Raphael, Cannes, Antibes, and Nice.

The west and south-west coasts of Italy possess many good localities for sea-bathing for those requiring, or at all events bearing, heat, such as Bordighera, Alassio, San Remo, Castellamare, Sorrento, and the islands of Capri and Ischia on the west and south-west coasts, and besides Venice, with the Lido, Ravenna, Ancona, and others on the east coast.

On the coast of Belgium, Holland, and Germany the most important localities are Blankenbergh, Ostend, Scheveningen, Heligoland, Borkum, Nordener, Baltrum, Langeroog, Spikeroog, Wangeroog, Dangast, Cuxhaven, Wyk, and Westerland.

The shores of the Baltic possess many delightful localities, such as Heringsdorf, Putbus on the island of Ruegen, Warnemuende, Travemuende, Doberan; but the sea-baths and the climate are less stimulating than on the shores of the German Ocean.

The coasts of Norway, Sweden, and Denmark offer likewise good opportunities for sea-bathing combined with bracing sea-air from July to September.

HERMANN WEBER.

SEA-SICKNESS.—SYNON. : Fr. *Mal de Mer*; Ger. *Seekrankheit*.

DEFINITION.—A functional disturbance due to the motion of a ship, manifesting itself principally in epigastric discomfort, frontal headache, giddiness, vomiting, and vasomotor changes.

ÆTIOLOGY.—It is well known that many persons suffer from giddiness and even vomiting on swinging, dancing, and other rapid movements; and that in persons in whom vomiting is readily induced, objectionable odours, moving objects, slight derangements of the alimentary tract and mere recollection of previous attacks are any of them liable to cause this condition. It is no matter for surprise that all these incentives to vomiting should be regarded as causes of sea-sickness. That they have a predisposing and subsidiary influence in many cases is undoubted; nor can it be questioned that they may produce vomiting as easily on sea as on land. The smell of the engines will often cause passengers to vomit even though the sea be perfectly calm, and the recollection of previous attacks may give rise to nausea and even to vomiting before the ship has left the harbour. But these are only predisposing causes, and vomiting due to them is not true sea-sickness; in this condition movement alone is the exciting cause. Thus it may be induced during sleep, the patient waking to find himself in the act of vomiting. Much discussion has arisen concerning the conditions of movement under which sea-sickness is most likely to occur, and there seems to be a general consensus of opinion that the essential factor is suddenness of movement or change in the kind of motion, especially the commencement of the descending movement as the ship pitches or rolls—the movement being in all cases different in kind from that to which the patient is ordinarily exposed on land. It has been pointed out that the sudden descent of a lift or the sudden arrest of the

movement of a train may produce in the epigastrium precisely the same sensation as does the sudden downward pitch of a ship, while on the other hand the movement of a swimmer in the roughest sea never produces sea-sickness. Women suffer more severely as a rule than men. Probably no one is absolutely immune. Old people and young children are generally but slightly affected, and persons who vomit easily from causes such as those mentioned above are especially prone to true sea-sickness.

SYMPTOMS.—A slight sensation of chilliness accompanied by pallor is usually the earliest symptom. Almost simultaneously with this the sufferer is conscious of feeling ill at ease and of a desire to remain absolutely undisturbed. Unpleasant sensations as of a tight band over the forehead and of retraction at the epigastrium, especially marked on each descent, are soon experienced. The breathing becomes irregular, owing largely to an unconscious fixing of the muscles at the time of any sudden change in movement. Regular, deep breathing, if persisted in, may postpone the progress of the symptoms for a short time; but sooner or later the feeling of chilliness becomes rapidly worse, giddiness supervenes, and an attack of vomiting and retching soon follows, to be succeeded by a sensation of returning warmth accompanied by dilatation of the cutaneous vessels and slight uniform improvement. The former condition, however, soon recurs, the subsequent attacks of vomiting being progressively worse and the intervals between them shorter.

In many cases there is no headache beyond that already described; but in others, and especially in those liable to headache or in whom the conditions already quoted as predisposing causes readily produce vomiting, headache and giddiness may become most distressing symptoms and may be continuous throughout the whole of the illness. At first the vomit consists of any food which the stomach may contain; later on it becomes greenish yellow, and even bright yellow, with a bitter taste, and consists principally of bile and mucus. During the period of vomiting the heart's action is occasionally irregular. Some people in whom the general distress is very marked vomit but little; hence it is often said that of persons who are sea-sick those who vomit feel better than those who do not. There is frequently a marked tendency to drowsiness, but refreshing sleep is practically unknown during the acute stage. Prolonged retching is occasionally accompanied by hæmorrhage, usually from the pharynx or œsophagus, but sometimes under the conjunctiva and into other tissues as in whooping cough. Diarrhoea is sometimes present, but constipation is more usually met with. The flow of saliva is increased while the urinary secretion is lessened. Appetite is lost, even the sight or smell of food being loathsome. The secretion of milk is frequently arrested in nursing women; in others the menstrual flow is augmented. Sea-sick patients are always worse in the morning. In three to five days a favourable reaction generally takes place, the vomiting and nausea cease spontaneously, appetite returns, and the patient feels well.

In a few instances great exhaustion supervenes rapidly or gradually. The patient feels miserably helpless. He suffers from coldness of the extremities, thirst, headache, and spasmodic pain in the stomach, and complains of numbness of the surface of the body. A semi-comatose condition,

from which the patient is with difficulty roused, is sometimes met with in very severe cases, and requires assiduous treatment. In prolonged cases the reaction may assume a febrile character, with a rapid pulse, flushed face, and hot skin; convalescence is then slow.

An occasional but rare and dangerous form of sea-sickness is swooning without vomiting or any other symptom. The patient thus affected may lie motionless and almost death-like for a variable period. In long voyages attacks due to recurring bad weather generally tend to assume a milder character. There may be giddiness with or without nausea, but no vomiting; and in any case the duration of the attacks will probably be brief.

DURATION.—The ordinary duration of sea-sickness in long voyages is from three to five days, but it may last for weeks. After short voyages, such as crossing the English Channel, most persons recover as soon as they land; others after sleep or food. A few convalesce more slowly, and giddiness may persist for some days.

COMPLICATIONS AND SEQUELÆ.—Fainting and hysterical attacks are the most common complications of sea-sickness in women. Pregnant women occasionally abort. A weak and irritable condition of the stomach, or a state of general debility, may remain for a long time.

PROGNOSIS.—This is almost invariably favourable; yet death, although extremely rare, may occur from syncope or from exhaustion. Patients with heart-disease incur no exceptional risk.

PATHOLOGY.—The equilibrium-apparatus appears to be the essential seat of the disorder. Thus the derangement is common to all those animals in which this apparatus is similar to that of man; it is produced by movements involving considerable deviations from the normal conditions of equilibrium; and it returns on any marked increase of these movements, even when the sufferer has become more or less accustomed to them. The theories which attributed sea-sickness primarily to psychical or vaso-motor changes may be dismissed as inadequate. Rosenbach points out that a degree of tolerance of certain changes in equilibrium is established in each individual, that this varies in different cases, and that any marked excess of the movements to which each individual mechanism is adapted will give rise to the phenomena of sea-sickness. According to his view the semicircular canals play no important part, but 'in the epigastrium lies a mechanism which works as an apparatus regulating movement and balance, and giving information to the brain concerning the position of the body, the direction of the oscillation, and the acceleration of the individual parts.' Our knowledge of the mechanism which controls the maintenance of balance and of its relationship to other parts of the brain is insufficient to render any complete statement possible; but whether we regard the epigastrium as a source of information to the brain or as the seat of the first efferent signs of cerebral disturbance, it seems probable that a satisfactory explanation of the phenomena of sea-sickness must lie in the direction which Rosenbach has indicated.

TREATMENT.—In the treatment of sea-sickness it must be remembered that no single method will be successful in all cases; that in the case of a considerable number of persons treatment is at most palliative; and that the condition tends, after

a few days, to spontaneous cure. It will be convenient to discuss separately the measures advisable in (1) short and (2) long voyages respectively.

(1) *Short voyages.*—In voyages limited to a few hours the treatment is practically confined to prophylaxis, and consists in avoiding the predisposing causes, and in reducing the exciting cause to a minimum. To carry out the first of these principles, the digestive tract should be kept in thorough order for at least two or three days, and it is a good plan to avoid all indigestible articles of diet during that period, and to administer a mild aperient a day before 'crossing.' All fatigue at the time of starting should be avoided. Food should be taken about three hours before going on board. All possible means of imparting courage to the prospective sufferer should be employed, and it is probably because of the influence in this direction of small doses of stimulants that alcohol has obtained a considerable reputation. A flannel band should be worn round the abdomen, and every precaution taken to ensure warmth of all parts of the body. The position on the boat should be as far as possible central, exposed to the breeze but sheltered from hot sun and every source of offensive odour. The horizontal posture is the best, but a deck-chair is often as good if a more central position on the ship can thereby be obtained. Indeed, the question of position is largely determined by the character of the boat and of the weather, for the discomfort resulting from cold and wet and the sight of the sea is sometimes greater than that depending on the lack of fresh air and obnoxious odours usual in a cabin. An exciting book will often be of material assistance by absorbing the attention and preventing the reader from watching the movements of the boat on the horizon. Eating dry biscuits, chewing cloves, or sucking a lemon or any other sour fruit is often of material assistance, and an effort should be made to breathe regularly and deeply. When vomiting has once set in the best procedure as regards food varies in different individuals. In some cases it is found better to abstain until the completion of the voyage; in others, to persist in taking small quantities, even though they be almost immediately rejected. For extreme sufferers disposed to luxury, a chair balanced on the principle of a marine compass is said to be of considerable service.

The medicinal treatment of sea-sickness is very unsatisfactory. Several of those drugs presently to be enumerated will effect in occasional cases a complete cure; but in the majority of instances any given drug is likely to prove useless. Bromides, especially that of sodium given in half-drachm doses once or twice a day for two or three days before embarkation, are much advocated, but actual drowsiness may be produced without any amelioration of the malady. Digitalin (one-sixth of a grain three times a day) taken for two weeks has also its advocates. Chloralamide is occasionally of service, particularly in those suffering from weak cardiac action. Cocaine ($\frac{1}{4}$ gr. every two hours, three doses being taken before going on board) is probably the most reliable of all drugs. Phenacetin, caffeine, nitrites, chloral hydrate, and morphine are occasionally of service. In the administration of alcohol that form should be given which under ordinary circumstances agrees best with the patient. If vomiting of bile has occurred care should be taken

to empty the stomach just before landing, as the retention of bile in the stomach will retard convalescence.

(2) *Long voyages.*—On long voyages the same attention should be paid to the general health before starting, and in rough weather the same general precautions should be adopted. Of drugs, morphine is probably the most satisfactory, but should never be given in cases in which it is known to produce headache and other unpleasant after-effects. The diet should be carefully regulated and food taken frequently and in small quantities. It has been recently urged by Rosenbach and other authorities that the equilibrium-apparatus should be trained by passive movements similar to those of the vessel before going on board. There is reason to suppose that this plan may be effective, but in persons in whom vomiting is readily induced it at best does little more than spread over the few weeks immediately preceding embarkation the discomfort which will be concentrated into the first few days of the voyage; and most persons will prefer to run the risk of the sea-sickness rather than to undergo the repeated giddiness which such exercises will almost certainly involve. The rest of the treatment for syncope, exhaustion, and other complications is on general principles. In very rare cases it may be advisable to land the patient.

H. MONTAGUE MURRAY.

SEA-VOYAGES.—Sea-voyages have from remote antiquity formed a mode of treatment in chronic diseases, especially of the respiratory organs, and have more lately been much recommended in the treatment of consumption and scrofulous affections; but the different influences to which the invalid is exposed on long sea-voyages are but little appreciated in their details by the majority of the public, or by medical men.

The essential advantages which are generally ascribed to sea-voyages are the enjoyment of perfectly pure sea-air, abundance of light, and free exposure to the sea-breezes; absence, or at all events great limitation, of bodily exertion; and the probability of psychical repose. The uninitiated frequently regard these advantages as more or less fixed and, so to say, measurable qualities, and speak of sea-voyages in the same way as of sea-bathing, cold-water treatment, mineral-water cures, or mountain climates. The advantages of sea-voyages are, however, by no means fixed qualities, and they are often mixed up with unfavourable influences, such as bad weather, sea-sickness, improper food, &c. In everyday life it is an acknowledged fact, and not less so in all climatic cures, that the house in which the invalid lives exercises a most powerful influence on his chance of regaining and maintaining his health; and that the house alone often mars the effect of the best-adapted climatic change. In the same way the floating house, the ship, with its arrangements, forms one of the most important elements in the compound agent 'sea-voyage.' The arrangements of ships, however, are notoriously often very imperfect, and the narrow cabin never stands comparison with a good bedroom, the only counterbalance to this drawback often being that the invalid is forced to be the whole day long on deck, that is, in the open air, in order to escape from the confined state of the cabin. By this circumstance alone, however, the majority of the more serious cases ought to be excluded from

sea-voyages in ordinary ships, as they cannot be easily moved from the cabins to the deck, and *vice versa*. The hygienic conditions of the ship, the space allotted to each passenger, the ventilation of the rooms, the arrangement of the decks, must in every case be a matter of careful inquiry; but it would require too much space to enter into the details in this place. There are iron and wooden ships, steamers and sailing vessels. The iron ships have the advantage of being easily kept clean and free from smells, but they are apt to become very hot under the influence of the tropical sun. The sailing vessels can be kept more free from smoke and dust; but they are dependent on wind, and if they meet in the tropics with perfect calms (doldrums), the passengers may have to endure intolerable heat for several days and possibly weeks. The combination, therefore, of sailing power for ordinary conditions, with steam to be used only in case of need, would appear to possess the preference for ships to be used for therapeutic purposes (invalid ships).

A second point of paramount importance for every delicate person is the food, and in this respect again the ship-life on long voyages is less advantageous than the life in well-supplied health-resorts or at home.

Sea-sickness, or rather the degree of liability to sea-sickness, depends on peculiarities of constitution, which are only to be recognised by exposure to the influences of the open sea in different states of agitation. See SEA-SICKNESS.

In the article on SEA-AIR the prominent qualities of sea-climates have been given; but the most cursory consideration of the climatic conditions to be encountered in a long sea-voyage shows that there must be great differences between the physiological and therapeutical influences of sea-climates in latitude 50° and in latitudes 15° and 5°. The air in the tropical regions has a much higher temperature, and a larger amount of absolute moisture; the atmospheric movement is, as a rule, though by no means always, slighter; the barometric pressure is somewhat less in the tropics than in the temperate zones; and the daily and annual variations of atmospheric pressure are greater in the former than in the latter. There is also a difference between the same degrees of latitude on the north and south of the equator, the temperature in the southern hemisphere, for instance, being somewhat lower than in the northern; but these differences are comparatively small. The effects on the constitution of the climatic conditions of sea-life in different latitudes are very complicated. We will here only point to a few facts, namely, that in some delicate constitutions the functions of life are performed more easily under the influence of greater heat; that many delicate persons can eat and digest better, are able to take more exercise, sleep better, and that their mental functions are more active under the same circumstances; but that in the majority of average persons continued great heat produces lassitude, a tendency to diarrhoea and other digestive derangements, and imperfect sleep. Further, that in most individuals the bodily temperature rises above the natural heat (in general about $\frac{1}{2}^{\circ}$ F., and in some exceptional persons as much as 2° and 3° F.); and that pulmonary hæmorrhage occurs more frequently under high than under ordinary degrees of heat. Morbid states accompanied by pyrexia and by a tendency to pulmonary hæmor-

rhage ought therefore not to be exposed to tropical heat.

The climatic conditions to be met with in different voyages through the same regions vary at different seasons, but they vary still more in voyages through different seas, especially according to the longitude and latitude. Faber showed that the equability of sea-climates is by no means so complete as is generally assumed; and that great changes in temperature and atmospheric movements occur not rarely on successive days, and even on the same day.

THERAPEUTICAL USES.—The opinions of different writers on the therapeutical value of sea-voyages in the treatment of disease vary considerably. The majority of physicians entirely, or almost entirely, confine themselves to diseases of the respiratory organs in recommending sea-voyages; but their therapeutical field is no doubt much larger, and the result is probably more generally favourable, in some other complaints.

1. *Phthisis*.—The writer has had the opportunity of witnessing the effects of sea-voyages, of two to seven months' duration, in 72 cases of phthisis, mostly in the first or the beginning of the second stage. Of these 72 cases 38 benefited considerably, 18 remained about stationary, 16 became worse. Of the 16 bad results, 7 occurred in patients who went to Australia and back, with scarcely any rest on land; they seemed to have gained in the first part of the journey, but more than lost the gain in the latter part, apparently from dislike of food, from the monotony of the life, and from exhaustion. Out of 36 cases in the first stage 29 were more or less improved, 4 remained stationary, 3 lost ground. Of 27 cases in the second stage the result was favourable only in 8 cases, indifferent in 11, bad in 8 cases. Of 9 cases in the third stage the result was bad in 5 cases, indifferent in 3, favourable in 1. The writer has also notes of 11 cases of phthisis in the first and the beginning of the second stage, in which long summer voyages (namely, from three to five months) with whalers to the northern seas were tried, the result being favourable in 9 cases, indifferent in 1, and unfavourable in 1, apparently through inability to bear the want of variety in food. Among the 72 cases 12 were females, of whom only 3 were improved, while 5 remained stationary and 4 lost ground. Almost all the female patients expressed a strong opinion that long sea-voyages are not suitable for female patients.

2. *Laryngeal and Bronchial Catarrh and Asthma*.—In simple chronic catarrh of the larynx, sea-voyages, or cruising in yachts from this country to the Mediterranean, to the Azores and Madeira, had very good results in 20 cases out of 24. The effect of a similar plan was also satisfactory in 11 cases of chronic bronchial catarrh. In a tendency to bronchitis from pulmonary emphysema the benefit was likewise evident in 10 cases out of 12; but here the effect was, from the nature of the circumstances, less permanent. Of 8 cases of asthma, 2 cases of a bronchitic kind were benefited; 2 of a nervous character aggravated; and 4 were neither better nor worse. Eight cases of hay-asthma were, while on the high seas, quite free, but those who returned while the complaint was still in season, were immediately attacked.

3. *Scrofula*.—In 15 cases of scrofulous affections (caries of bones, affections of joints, glandular

swellings and ulcerations) one or several long sea-voyages were tried; in 11 of them the effect was quite satisfactory, in 4 less decided.

4. *Vesical Disease.*—In 3 cases of irritable bladder sea-voyages on yachts in warm climates have likewise proved useful.

5. *Cardiac Disease.*—Decidedly injurious was the effect of sea-voyages in 5 cases of dilatation of the heart, combined with chronic bronchitis. In 2 cases of enlargement of the liver, connected with weakness of the heart, the result was likewise unsatisfactory.

6. *Skin-disease.*—Chronic eczema was, in 5 cases out of 6, aggravated by sea-voyages.

7. *Nervous disorders.*—In 4 out of 6 cases of mental irritability, long sea-voyages, especially in yachts, had favourable results; in the fifth the mental condition was aggravated; in the sixth great improvement of the mental state was obtained, but this was accompanied by considerable exhaustion, from inability to take a sufficient amount of food. Of 4 cases of melancholia, 2 were apparently cured, the third remained uninfluenced, and one committed suicide by jumping overboard. In 4 cases of *tabes dorsalis*, in the earlier stage, cruising in comfortable yachts in the Mediterranean, with occasional landing, during the autumn, winter, and spring months, has been very beneficial; in 2 of these the disease has apparently been arrested, by persevering with this course during fifteen and sixteen years.

8. *Dipsomania.*—Finally, the writer has tried long sea-voyages in yachts in 5 cases of dipsomania, stimulants having been entirely excluded from the dietary. In one of these cases the result appears to be permanently good; in the 4 others it was good for the time with regard to the state of the body as well as of the mind, but there were relapses, which in 2 of the cases have led to several repetitions of the trial, each time apparently with more lasting, but as yet no permanent, result. Well-arranged sea-voyages deserve, therefore, at all events, a place in the management of this most terrible affection.

CONCLUSIONS.—From a comparison of these experiences with those of other observers, the writer is inclined to infer that, under favourable circumstances, sea-voyages of not too long duration may be rendered beneficial in the early stages of phthisis occurring in persons with a strong constitution, and without great tendency to sea-sickness. The voyage to Australia and New Zealand and back, after a stay of a few months in these climates (Hobart's Town, in Tasmania, for instance), specially recommends itself. The invalids referred to left in the second half of September, or in October or November, and returned in May or June. In this way the more unfavourable seasons of England are avoided, and instead of the short and sunless days, long and bright ones are obtained. To go to Australia and to return immediately has proved exhausting in several instances.

The voyage to the northern seas requires a peculiar mental disposition, and would, under the present conditions, be resorted to only under exceptional circumstances; but it has been very beneficial in the 9 cases of early phthisis mentioned—all of them possessing a satisfactory fund of strength, combined with love of sea-life and a good digestion.

The combination of yachting in the Mediterranean, and residence at one or several of the health-resorts

of those regions, or with a visit to Upper Egypt, has repeatedly proved successful in cases under the observation of the writer, not only in pulmonary invalids, but also in cases of mental irritability, exhaustion, chronic rheumatism, chronic glycosuria, and gout. This plan, however, is somewhat expensive. The patient ought to be, while in Egypt, under constant medical superintendence.

In hay-asthma, sea-voyages during the season of the complaint are to be recommended; but in other forms of asthma the result is uncertain, and the advice should not be given without consideration of all the circumstances. In most cases of younger persons alpine climates deserve to be preferred to sea-voyages.

In some forms of mental irritability, in overwork, in anxiety about business, and in the earlier stages of locomotor ataxy, sea-voyages, and especially yachting, in the subtropical regions, offer many advantages, particularly during the colder and damper seasons of our climate, as they allow of the combination of the enjoyment of sunlight and pure air with rest of body and mental repose. In slighter forms of mental irritability or overwork, shorter voyages are often sufficient, and even preferable; and the voyages to Madeira, to the West Indies, or to Brazil and the River Plate, may thus be recommended during the colder season.

Dipsomania and other morbid habits may be treated with great advantage by sea-voyages and yachting, provided that stimulants and the other injurious influences which the weak person is unable to resist can thus be entirely removed.

The time is coming when we shall have *therapeutic ships*, specially arranged for different classes of invalids. It would, for instance, not be wise to mix those suffering from dipsomania with sick persons to whom a moderate amount of stimulants is useful.

CIRCUMSTANCES COUNTER-INDICATING SEA-VOYAGES.—The circumstances which render it necessary to avoid sea-voyages are:—

1. Unconquerable sea-sickness.
2. Great temporary or permanent weakness and exhaustion.
3. Permanent delicacy of appetite, with inability to become accustomed to a certain monotony of food, or to a certain coarseness in the preparation of food.
4. Inability to bear the glare of the sea, such as occurs in tendency to glaucoma.
5. Persistent sleeplessness while at sea.
6. Dilatation and weakness of the heart, with or without valvular disease.
7. Enlargement of the liver, especially when caused by dilatation of the right ventricle.
8. Advanced stages of consumption, unless the affection be quite stationary.
9. Morbid conditions with a tendency to pyrexia.
10. A tendency to hæmorrhage.

It is the influence of great heat that ought to be avoided by the two classes of cases last mentioned. A voyage through tropical seas, especially in sailing ships, might prove dangerous in such subjects, from the possibility of being becalmed.

11. A tendency to epilepsy or maniacal fits. This ought specially to contra-indicate sea-voyages to tropical climates.

An ungrammatical synonym for steatorrhoea. See STEATORRHOEA.

SEDATIVES (*sedo*, to calm).—SYNON.: De-

pressants; Fr. *Sédatifs*; Ger. *Beruhigende Mittel*.

DEFINITION.—Agents which soothe pain and diminish functional activity. The term is often made to include other important therapeutical groups, as hypnotics, anæsthetics, and narcotics, i.e. all drugs which depress the sensory apparatus. See NARCOTICS.

1. *Local Sedatives*.—This class includes all agents which diminish the sensibility of the skin. Among these are cocaine, eucaine, aconite, carbolic acid, ice, ether-spray, atropine, menthol, morphine, veratrine, chloroform, and chloral hydrate. They act by paralysing or depressing the terminals of the cutaneous nerves, and are indicated in superficial neuralgias and in local subcutaneous inflammations, where they may be simply painted on in solution, or injected hypodermically or used by the old endermic method after the cuticle has been removed by blistering with ammonia. Profound cutaneous insensibility may be produced by the ether-spray or cocaine, which enables the surgeon to perform minor operations without pain. Chloride of ethyl is also very valuable as a local anæsthetic. See ANÆSTHESIA, LOCAL.

2. *General Sedatives*.—This class includes all agents which depress the functions of the cerebrum, and in the more accurate nomenclature of the new pharmacology the term 'general sedative' is fast disappearing, the group being now scattered among the hypnotics, such as sulphonal, trional, paraldehyde, chloral hydrate, bromides, &c., which are indicated in simple insomnia, and among the narcotics as opium, morphine, alcohol, Indian hemp, hyoscyamus, &c., which before depressing the sensorium cause some excitement. These agents are used to relieve pain and produce sleep. The drugs which produce total loss of consciousness with abolition of reflex action were formerly grouped under the term 'general sedatives'—these are now always defined as general anæsthetics, and include chloroform, ether, nitrous oxide, methylene, &c.

3. *Cardiac Sedatives* are drugs which diminish the force of the ventricular contractions, and at the same time reduce the pulse-rate. The principal agents employed for this purpose are tartar emetic, aconite and veratrum viride. They act upon the vagus-centre, the cardiac ganglia or the ventricular walls, or upon all these structures, and they are indicated in short sthenic inflammations, as in the fever accompanying tonsillitis, pneumonia, or orchitis, and in the rare conditions in which the heart's action becomes rapid and tumultuous without weakness of the ventricle.

4. *Pulmonary Sedatives* depress, and in large doses paralyse, the respiratory centre. By soothing this centre, any excessive or useless coughing can be prevented. Stramonium, belladonna, datura, and the numerous remedies for asthma act by diminishing the sensibility of the vagus-terminals in the lungs, though the respiratory centre may be stimulated by them. The chief pulmonary sedatives are

opium, morphine, chloral hydrate, codeine, hydrocyanic acid, chloroform, Virginian prune, &c. There are few better instances in the realm of therapeutics of the great danger of using a misleading classification. Pulmonary sedatives are frequently confused with sedative or depressant expectorants, but their actions are widely different. Given, for example, a case of bronchitis with dyspnoea from the difficulty of expelling a viscid secretion in the finer tubes, one full dose of a pulmonary sedative may cause death by depressing the respiratory and cough-centres, while a few doses of a sedative or depressant expectorant like ipecacuanha or antimony, by increasing and liquefying the tough and scanty secretion, may save life.

The pulmonary sedatives are indicated in all irritable conditions of the respiratory and cough-centres in which there is no great bronchial secretion, i.e. in the cough of acute pleuritis, in the early hacking cough of tuberculosis, and in all conditions where the patient is coughing a great deal more than is really necessary for expectoration. They can be combined often to great advantage with depressant expectorants.

5. *Gastric Sedatives* are a most important class of remedies; they act chiefly locally by soothing the inflamed or irritable gastric mucous membrane. The chief are morphine, cocaine, hydrocyanic acid in small doses, creosote, carbolic acid, all the preparations of bismuth, oxalate of cerium, chloroform, atropine, and ice. Gastric pain and vomiting are the chief indications for their use; they should be generally given before food and in frequently repeated doses. Sometimes minute doses of arsenic, and nitrate of silver, are employed as gastric sedatives. Small doses of morphine with prussic acid given in a plain effervescing mixture along with ice and in conjunction with a blister or smart sinapism to the epigastrium will generally control pain, nausea or vomiting of local origin.

6. *Spinal Sedatives* are agents which depress the functions of the cord chiefly by diminishing the activity of the anterior cornua. Though a long list of official agents produce this effect, few are employed in medical practice with this aim. The most reliable are bromides, physostigmine, chloral hydrate, chloroform, ether, camphor, nitrites, alcohol in large doses, salts of silver, copper, zinc and arsenic, gelsmium, antimony, ergot, apomorphine, &c. The chief indication for their use is spasm, whether this be tonic or clonic. The ideal condition calling for the exhibition of this group of therapeutical agents would be seen in a case of strychnine-poisoning, and the writer has found that in this formidable emergency no drug is so reliable and safe as very large doses of alcohol which antagonise the stimulating action of the strychnine upon the anterior cornua of the cord without dangerously depressing the heart at the same time.

7. *Vesical Sedatives* are drugs which on being eliminated by the urinary tract act as sedatives to the irritable mucous membrane of the bladder. They are indicated in cystitis from whatever cause. The most important are boric acid, hyoscyamus, belladonna, buchu, pareira, uva ursi, santal oil, copaiba, benzoic acid, &c.

SENILE INSANITY.—*See* p. 761.

SENILITY (*senex*, an old man).—**SYNON.**: Senile Marasmus; *Fr.* *Vieillesse*; *Ger.* *Greisenalter*.

DEFINITION.—That condition of body which usually supervenes naturally after the seventieth year, but sometimes occurs prematurely.

Senility is separated from the previous period of maturity by the climacteric stage, which in men occurs between the ages of fifty and sixty, and in women about ten years earlier. When of premature occurrence this state is commonly hereditary, or secondary to some exhausting illness, where failure of the trophic influence of the nervous system has been marked. All the signs and symptoms of senility have been seen in individuals under twenty years old.

We do not know why the body, after it has reached a state of maturity and vigour, should gradually decline; why, when once an even balance between tissue-waste and restitution is established, it is not maintained indefinitely. How far the failure is due to some inherent tendency, and how far to external influences, is wholly conjectural. Among the most recent hypotheses is one based upon the theory that the various glands, secreting and ductless—and also perhaps some of the tissues—exert some material influence upon the blood, and through it upon the tissues generally, whereby the normal metabolism of healthy activity is maintained; and, conversely, as this influence—effected, as is supposed, through some ‘internal secretion’—fails, so does the general nutrition deteriorate. According to Brown-Séquard, the weakness and characteristic phenomena of old age are due to ‘a natural series of organic changes and the gradually diminishing action of the spermatic glands and ovaries.’ To refer the senile state to an impairment of the trophic influence exerted by the nervous system, or to a diminution in the water contained in the protoplasmic elements of the tissues, or to any other such cause, however true each and all may be so far as they go, only places the difficulty a step farther back, and does not remove it.

ANATOMICAL CHARACTERS.—Observations, especially those of Humphry, have shown that many of the morbid conditions which are usually regarded as essential features of advanced life are really manifestations of disease occurring at this period, and do not of necessity pertain to senility, which may supervene and progress to death undisturbed by any actual disease—in short, an old age that is healthy, just as any other period of life may be. The term ‘involution’ has been suggested to express the normal senile changes in the tissues and organs, of which a progressive *atrophy*—a simple diminution of material—is the most universal and characteristic. The degree of wasting varies, but there is a general diminution in body-weight and height, except in persons whose climacteric has been marked by an increase of the adipose tissue, when the total loss of weight may be inconsiderable. Among the organs which exhibit simple

atrophy in the highest degree are the brain and spinal cord, the shrinking of the former with increase of the subarachnoid fluid being sometimes very considerable; the generative organs, especially the ovaries, and to a less extent the testes, the uterus, and the mammary glands; the mucous membrane and glands of the digestive tract; the bronchial and vesical mucous membranes; the spleen and lymphatic glands, the latter even to complete disappearance; and the kidneys. A most important change, and one that exerts a very direct influence on nutrition, is an extensive shrinking or even obliteration of the capillaries in almost all the tissues. The skin becomes much diminished in thickness, especially in the papillary layer, the constituent papillæ being very indistinct; and loss of hair and change of colour are well-known features. The senile changes in the skeleton are of peculiar interest. The bones, which in the earliest stages of formation are solid, become, as development proceeds, hollowed internally, by the formation of cancellous tissue, and, in the long bones, of the medullary canals. As the absorption of the central part proceeds the bones nevertheless increase in weight and bulk until maturity is reached by subperiosteal ossification; but in the decline of life, as this process takes place scarcely at all, and the atrophy continues, the bones, while retaining their general size and form, become much thinner, lighter, and weaker. The change takes place especially in the cancellous parts, which are most vascular, and where the agents for absorption are most active—hence the special weakness of the ends of the long bones and their liability to fracture. The alveolar parts of the upper and lower jaw-bones, consisting as they do chiefly of this loose spongy tissue, are characteristically wanting in the aged; and, since these parts carry the teeth, this atrophy of the bone leads to their falling out. The lower jaw is one of the few bones in which an alteration in shape takes place, the ramus and body coming to be more nearly in a straight line, with proportionate widening of the angle. The bone thus resembles the shape it has in the infant, with the difference that it then consists mainly of the alveolar part, while in old age it is the denser basal or sub-alveolar part that alone remains. The altered shape of the mandible has been attributed to the loss of teeth causing a deviation in the line of action of the masticating muscles. Humphry found no confirmation of the commonly accepted statement that the angle between the neck and shaft of the femur becomes smaller with age. The same observer has drawn attention to two exceptional conditions of an opposite character met with in the skull. One of these occurs as nearly symmetrical areas of atrophy of the outer table and diploë, forming well-marked depressions extending obliquely across the parietal bones, which he is inclined to attribute to ‘the pressure of the occipito-frontalis tendon stretched upon, and playing over, the most prominent part of the vertex.’ The other condition he has described as a considerable thickening of the calvaria, especially towards the frontal region, with great density of the bone. The explanation of this very anomalous state, so contrary to what takes place in the cranium and entire skeleton generally, is not obvious, though it may be connected with the diminished pressure of the wasting brain. The age at which these changes in the osseous system set in is very variable, but they

commonly commence earlier in women than in men. Slight atrophy takes place in the cartilages, costal and articular, the latter accounting for the diminution in height of the old person; but calcification is not invariable, and is indeed evidence of disease. Corresponding to the loss of strength in the bones is an increasing weakness in the power of the muscles, which explains, *inter alia*, the fact that fracture by muscular action is no more frequent in the aged than at other periods of life. It is to the weakening of the dorsal muscles that the stoop of age is attributable.

Associated with this atrophy it is usual to find *degenerations*—fatty, calcareous, or pigmentary—all of which are to be regarded as evidences of deficient nutrition, and may be contrasted with the differentiation and growth which characterise the commencement of life. The arcus senilis, the atheroma and calcareous degeneration of the vessels, the calcification of cartilages, the fatty degeneration of muscular and glandular epithelial tissue, the deposition of pigment in some spots, and the deficiency of the same in the hair and skin of the coloured races, are illustrations of true degenerative changes. Inasmuch, however, as these conditions are frequently wanting even in persons dying at an advanced age, they cannot be regarded as essential characteristics of senility; though it may be admitted that the cause, whatever it be, that determines the above described simple atrophic changes might easily be supposed to favour the closely allied states of degeneration. It might, indeed, be reasonably argued that it is the very absence of these and other degenerative changes which permits the attainment of great age, while their occurrence, as is usual, at a somewhat earlier period tends to a rate of mortality below that of these advanced ages.

Another expression of impaired nutrition, not so profound perhaps as degeneration, is a fibroid overgrowth in certain tissues, especially the arterial coats, which are often much thickened therefrom, and the prostate gland, which is commonly enlarged in elderly men from this same morbid change—the so-called hypertrophied prostate. The meninges, and the capsules of the liver and spleen, are sometimes thickened from the same cause; and a similar cirrhotic condition may be set up in the kidney and testis.

The blood contains fewer corpuscles and less solid constituents, is more watery, and is said to coagulate more readily. The total quantity is less.

The semen is very frequently wanting in spermatozoa, and contains in their place granular fatty cells, like colostrum-corpuscles, with a few red blood-corpuscles; but this is not invariably the case, for perfect spermatozoa are occasionally met with at an advanced age.

PHYSIOLOGICAL CHARACTERS.—The results of such structural imperfections appear in deterioration of the purely physical, as well as of the specially vital, properties of the tissues. There is an increased rigidity in some parts, as the tendons and blood-vessels; and a diminished cohesion in others, as the nails and bones, which are brittle and easily broken. Perhaps the most prominent and distinguishing mark of old age is a loss of elasticity; the skin, cartilages, blood-vessels, and lungs show this to a very marked extent, in the wrinkled integuments, dilated vessels, and distended air-cells. It has been noticed that this dilatation particularly affects the thin-walled veins, and more especially

those which do not run with arteries, are more superficial in position, and are concerned less with nutrition than with the proper return of blood—the ‘derivative circulation’ of Sucquet. The advantage of this is apparent, for such an arrangement must be a safety-valve in the case of the brain, to which organ there is a liability to determination of blood, and where the vessels are apt to rupture; hence the frequent turgescence of the nose and ears, and development of the veins of the dlopœ, in the aged. The muscular contractility and nervous irritability are diminished; and atrophy and degeneration of the gland-cells lead to failure in their powers of secretion.

The heart’s beat is weak, and frequently intermittent, from defect in rhythmical nervous stimulation; the cardiac sounds are feeble and often altered; and there is a general tendency to venous congestion. The mean rate of pulse after the age of sixty-five years is 75, gradually diminishing to 70.

The tissues, which differ in chemical composition from those of mature life, must in their metabolism form different products of waste; while the altered blood, circulating in a restricted area with diminished force, must offer to the organs a different pabulum from that which they have hitherto received, supplied as it is by impaired digestive organs. The enfeebled respiration prevents complete oxidation; and the excretory organs, being less capable, but imperfectly withdraw from the body the results of metamorphosis. The quantity of urine is often diminished to fifteen or twenty ounces *per diem* in old men enjoying good health. It contains a total amount of solids less than the normal standard, but the urine itself may be relatively of higher specific gravity, and deeper colour, from its diminished quantity.

As the nutritive functions fail, so do those of the neuro-muscular system. The sense-organs imperfectly receive impressions, which are but dimly communicated to the sensorium, whence feebly emanate the impulses needful to determine movements in muscles, the protoplasmic contractility of which is gradually diminishing. Meanwhile, the higher mental qualities, such as memory, judgment, and reason, dependent as they are upon the most perfect nutrition, gradually fail. The opposite conditions of wakefulness and drowsiness are frequently met with, and seem to be due to brain-wasting, as well as to some change in the cerebral circulation.

As a further manifestation of the lowered vitality, recent careful and continued observations have shown that the average body-temperature is slightly lower than it is in adult life, and the power of resisting cold is diminished.

The power of reproduction, lost by women at the climacteric, before the stage of senility sets in, is occasionally preserved by men to an advanced age.

Thus the old man presents a strong contrast in his vitality to that of the child; for while the life of the latter is so largely dependent upon, and so readily responsive to, external or peripheral impressions, the former lives more and more within himself; the distinctive animal functions gradually failing, as his existence becomes restricted to the performance of those of self-nutrition. The progressive impermeability of the capillaries, and the lessened vitality of the skin, alike tend to withdraw from the surface towards the central organs the manifestations of life.

Diseases of Old Age.—In a certain number of cases, the progressive deterioration in structure and failure in functional capacity mutually adapt themselves, and produce an old age which may be as healthy as maturity or childhood may have been. But in the course of the atrophic changes which normally mark this period, the body is liable to certain influences, both intrinsic and extrinsic, which lead to diseases characteristic of this stage of life, as there are those of infancy and puberty. Death from old age, when the organs have gradually and uniformly failed, is not unknown, but the fatal end is more commonly due to some disease, which has either lasted from an earlier period, or is especially the acquirement of this stage.

The maladies particularly characteristic of old age are marked by certain general features, which they owe to that condition of nutrition in which the tissues are at this period. Thus, as a rule, they present but little activity in their progress, or but slight severity in symptoms, though they are none the less likely to bring about a fatal result, from the ill-resisting power of the whole system. Diseases of an acute character are rare at this time, and such as do occur assume an adynamic form, and are very liable to run a most insidious and even latent course. When once established, an illness tends more perhaps towards maintaining an isolated attitude, without those sympathetic disturbances of many other organs which are so prominent in children. The power of reaction possessed by the aged is but very slight; owing to this, diseases readily lapse into a chronic state, or even present a chronic character from the outset, while comparatively trifling causes may lead to serious results. The observations of Humphry, however, went to show that the reparative power even in persons of advanced age is often greater than is supposed, and he adduces well-authenticated cases of complete recovery from severe accidents and illnesses; in such cases we may reasonably infer that the degenerative changes are wanting or but very slight.

There is probably no single disease which is met with in advanced age only; rather is it the case that many diseases which prevail at certain periods of life are wanting in old age. The atrophy of every tissue and organ entails a general failure in function; and should this failure predominate in any one system, as may readily follow from a marked degeneration of certain special parts, we have some exception to what may be taken as the normal standard of the senile state—in other words, a disease of it. The same difficulties surround the question, why one set of organs should be affected rather than another, as at other ages; but there nevertheless does exist a preference towards affections, of the nervous, circulatory, and respiratory systems. But a very large proportion of old people are entirely free from disease—of 824 persons over eighty years old, 55 per cent. of the women and 35 per cent. of the men were reported to be healthy.

Diseases of the brain.—The cerebral lesions may be a general senile wasting and softening, with complete enfeeblement of nerve-function; or of a more localised character, from rupture or occlusion of some vessel. The liability to venous engorgement is very prone to manifest itself in the brain, and cerebral congestion of varying extent is frequent. The cerebral vessels are especially liable to atheroma, and hence the great frequency of apoplexy in old age. The meninges are free from

morbid change beyond thickening, and offer none of the inflammatory conditions so common in early life. Muscular tremors especially involving the head are frequent, and are probably due to wasting of the cerebral cortex. All degrees of deafness and impaired sight are met with.

Diseases of the heart.—The degeneration of the cardiac substance may lead to a state of asthenia, gradually becoming fatal; dilatation of the orifices may be the more prominent lesion, with all the consequent symptoms of obstructed circulation; or they may be constricted, from atheroma or thickening of the cusps or rings. Cardiac dyspnoea and every form of irregularity in cardiac rhythm occur to variable extents.

Diseases of the lungs.—Pulmonary diseases are important, since they are commonly the immediate causes of death in the aged. A bronchial catarrh, or at least a considerable increase in the bronchial secretion, is a normal state in the very old; and this has been regarded as a compensation for the arrested skin-action. The transition from this to severe bronchitis is both easy and frequent, and is favoured by the liability to lung-congestion, and the enfeebled heart-power. Even more serious is a senile form of lobular pneumonia, which seems to be set up in the congested and oedematous areas, possibly as a further stage of the bronchitis. Such pneumonia is of very frequent occurrence, and often requires carefully looking for, since direct symptoms are wanting. When a generally ill-defined illness is present in an old person, this condition should be suspected.

Diseases of the digestive organs.—The digestive organs, supposing they have escaped the dangers of earlier periods, are not often the seat of disease at this time of life. The perversions of function they present, such as constipation and flatulence, may be conveniently comprised under the term 'atonic dyspepsia,' and are mainly to be attributed to deficient muscular power in the alimentary canal, and to a deficiency in the digestive fluids. Nevertheless, a good appetite and very fair digestion are far from being the exception in old people. An acute form of diarrhoea of a dysenteric character has been described as occurring at this period.

Diseases of the skin.—The skin, which suffers so much diminution in nutrition and thickness, often exhibits as a result marked changes in sensibility, even to the existence of an intolerable pruritus, no cause for which is visible. The scratching which is resorted to for relief sets up a dermatitis which intensifies the discomfort. The unhealthy integument offers a very favourable nidus for pediculi, and phthiriasis is accordingly a common senile affection.

Diseases of the urinary organs.—The most characteristic appearances in the senile kidney are those of a diffuse interstitial nephritis, with progressive atrophy of the tubes, similar in many respects to the 'gouty kidney,' but not, like it, associated with cardiac hypertrophy. The urine is in such cases albuminous, but the general symptoms of Bright's disease met with in middle life are usually wanting. Glycosuria, often intermittent, is of very frequent occurrence in old people; but is rarely attended by the constitutional disturbance of diabetes. Notwithstanding the very imperfect action of the skin and kidneys as excretory organs, diseases directly attributable to non-elimination of waste products are not characteristic of old age.

Irritability of the bladder, or even vesical catarrh, is very common in old men, being largely determined by the enlargement of the middle lobe of the prostate, but the hypertrophy of the organ may exist to a considerable extent without causing any symptoms until the mid-lobe is affected. Both retention and incontinence of urine follow, from the diminished tone of the viscus.

Vascular disease.—The frequency of atheroma of the vessels and thickenings from peri-arteritis has been alluded to. The tendency of the blood to coagulate, added to the opportunities it has for stagnating in the dilated channels and cavities of a weak heart, makes thrombosis and embolism very liable to occur in the senile state. The result of the obstruction is gangrene (*gangræna senilis*), which is readily established in tissues, the capillaries of which have wasted or are obliterated, with corresponding deficiency of nutrition.

Arthritic lesions.—Very few old people escape chronic arthritis in one or other of its many forms, though it may be questioned whether the constant pains complained of are not oftener due to neuritis than actual rheumatism. The fibrous tissues of the joints, fasciæ, and tendons are thickened, and less flexible from lack of moisture, with the result of producing that stiffness of the limbs so characteristic of the aged. The pain is rarely acute, but it is lasting, and aids in bringing about the general deficiency of motor power. True gout is scarcely a disease of old age, though often continued on from an early period of life.

Tuberculosis, Cancer, and Syphilis.—A senile form of tuberculosis occurring in people over sixty years of age, in whom the constitutional signs may have appeared in early life, with almost complete freedom during maturity, is met with. Marked evidences of this affection have been seen for the first time in persons over seventy-five years of age. The general features of this condition are similar to those in childhood, but slower in their course, more complete in the degeneration produced, and far more resistant to treatment. The cancerous and syphilitic cachexiæ very rarely manifest themselves for the first time in old age.

TREATMENT.—Old age itself, as a period of life, is clearly no more to be treated as a state of disease than life at any other stage. But regarded as a marasmus or cachexia, it has been sought to avert it as long as possible, or mitigate its effects; and for the attainment of longevity many means have been proposed, though as yet without any reliable result, the most diverse plans having been equally successful or futile. See PERSONAL HEALTH.

Based upon the hypothesis above mentioned, Brown-Séquard claims that much benefit to old men has followed the daily subcutaneous injection of a milligramme of a watery extract of the testis of an adult guinea-pig filtered through a Pasteur filter. Others have affirmed the same, but further confirmation is wanting.

It is unnecessary in the present article to explain the treatment of the diseases of old age, as appropriate remedies are set forth under the special headings. It is sufficient here to indicate that, whatever may be the malady, and whatever be the treatment pursued, it must not be forgotten that we are dealing with organs in which the structure is deteriorating, and the vitality of which is failing, and that all measures of a depleting or depressing

character must be avoided. The feeding of the aged, therefore, becomes a matter of the greatest importance. Speaking generally, the food should be of the most nutritious character, and given in small bulk and frequently. The old person, whether ill or well, should not be allowed to go for many hours without food, as is too often the case, through the night. A light meal in the small hours of the morning is of the greatest benefit, and goes far to counteract the wakefulness so common at this period of life. In view of the presumably deficient power of the digestive juices, some of the artificial semi-digested foods may be advantageously employed, or the active principles of the digestive secretions administered with the food. The need for alcoholic stimulants is usually imperative, especially for those who have always taken them, but they should only be given with other food. Medicinal tonics are seldom of the same benefit that they are at earlier ages; probably strychnine is of most value. A daily aperient, such as two grains or more of the extract of cascara sagrada, is frequently necessary; and it is generally undesirable to forbid any habit, whether of drugs, food, or smoking, which has been previously long continued. Among the most important hygienic indications is the maintenance of warmth. A fall in temperature both lowers the general vitality, and tends to establish a local disease, and its effects are more easily prevented than cured when once established. Warm clothing is therefore indispensable, and cold feet should be specially guarded against. Equally prejudicial with cold and damp is exposure to high winds, which is frequently responsible for a fatal pulmonary attack.

W. H. ALLCHIN.

SENSATION, Disorders of.—See OLFACTORY SENSE; VISION; OPTIC NERVE; HEARING; TASTE; TOUCH; and PAIN IN VISCERAL DISEASE.

SEPTICÆMIA (σηπτικός, putrid; and αἷμα, blood).—SYNON.: Fr. *Septicémie*; Ger. *Septicæmie*. See SAPRÆMIA.

SEQUELÆ (*sequor*, I follow).—Consequences or sequels. This word is applied to symptoms or morbid conditions which either remain or supervene after a disease has run its usual course; such as renal disease after scarlet fever, paralysis after diphtheria, or cardiac disease after acute rheumatism.

SEROUS FLUID.—See DROPSY, p. 417; and INFLAMMATION, p. 736.

SERPIGINOUS (*serpo*, I creep).—This term is used in connection with certain morbid conditions, such as ulcers or eruptions, when they spread in a creeping manner.

SERUM-REACTIONS.—When an animal, whether belonging to the human or other species, is suffering from, or has recently suffered from, a disease caused by certain of the bacteria which do not produce powerful extra-corporeal toxins, changes take place in the blood of that animal. These changes have been shown within recent years to be extremely complex, and the number of phenomena which result are considerable. To one of these phenomena, seen most especially in the blood, the name *Agglutination* has been given.

If two rabbits be taken, one normal, and the

other after inoculation on two or three occasions with a culture of the *B. typhosus*, upon mixing the sera of these rabbits with an emulsion of a young culture of the *B. typhosus*, and examining the mixture under the microscope, two very different pictures will be seen. The bacilli in the mixture made with the serum of the normal rabbit will be seen to be swimming about freely in the field, whereas those in the mixture made with the serum of the injected rabbit will be all herded together and motionless. This herding together is the Agglutination or Serum-Reaction.

HISTORY.—It was shown by Pfeiffer that when an animal was immunised by frequent injection of sub-lethal doses of an organism such as the *V. cholerae* or *B. typhosus*, the injection into the peritoneal cavity of a living culture of the organism against which the animal has been immunised was followed by disastrous results for the organism. Peritoneal fluid withdrawn at intervals, and examined under the microscope, shows that the bacteria after the lapse of a short time lose their shape, change into small round bodies, and finally disappear. The peritoneal fluid is now bactericidal. This bactericidal power is, however, specific (i.e. the fluid only kills the bacteria against which the animal has been immunised). After Pfeiffer had described this phenomenon, Gruber and Durham, and Bordet showed that the blood-serum of an animal so immunised has a marked effect upon the bacteria when mixed with it *in vitro*; in this case also the action is specific. Both these reactions were originally used for the purpose of determining the specificity of certain bacteria, but Gruber suggested that it was possible that it might also be used in the diagnosis of diseases produced by known bacteria. Grünbaum and Widal both began to work at this subject; both of them found that the surmise of Gruber was correct. Widal published his results first, and the reaction which is produced by the blood of an enteric patient upon typhoid bacilli is now known as 'Widal's reaction.' It has been since shown that the blood of patients suffering from other diseases will agglutinate the bacteria producing those diseases, and serum-reactions are now recognised as valuable aids in diagnosis.

CAUSE OF THE REACTION.—Little is as yet known as to the cause of the reaction, but it appears that after the injection of bacteria and the production of a certain degree of immunity, there are present in the blood of the injected animals certain bodies which are absent from the blood of normal animals. These bodies, which Gruber first called *Glabrificins*, are now known as *Agglutinins*.

According to Ehrlich's '*Seitenbentheorie*,' the immunisation of an animal is accompanied by the formation of a substance which he called 'immune body.' This body is able to fasten itself on to the bacteria which are injected subsequent to immunisation, and by so doing enable the Complement (which is present in the normal serum) to dissolve them and thus render them harmless to the animal. The agglutinins and this 'immune body' are not identical, because the 'immune body' may be formed in the absence of the agglutinins, and the agglutinins may be present and the 'immune body' absent: moreover, when both are present, there is no constant relation between them. It has been shown, however, that as a rule the two bodies are produced and increase together, and sometimes decrease proportionately. For instance, in pro-

portion as the serum of an animal increases in bactericidal power, so does the agglutinating power increase, while the spleen-juice of an enteric patient is both less bactericidal, and contains less agglutinins than the blood-serum. Although, as we shall see, the serum of many normal animals often possesses a slight agglutinating power, the agglutinins are a new product formed on account of the introduction of the bacteria, and have therefore a resemblance to the 'immune body.' The resemblance is still further marked when we remember that the agglutinins become anchored on to the bodies of the bacteria apparently in the same way as the 'immune body.' The reaction may therefore be considered to be one accompanying immunity rather than infection. What we should expect from this statement actually happens in fact; the reaction takes a certain time to develop in the serum after infection, and if there is no attempt on the part of the tissues to produce 'antikörpers' (i.e. immune bodies, agglutinins, &c.), the serum will never show the characteristic agglutination.

Outline of procedure.—As it is known that the serum of many animals, including man, possesses the power of agglutinating certain bacteria when it is undiluted or only slightly diluted, it is necessary to dilute the serum before mixing it with the culture of the bacteria.

In the case of man and the *B. typhosus*, for instance, it is found that about 30 per cent. of all persons possess a serum which will clump the bacteria when equal quantities of serum and a thin emulsion of the bacteria are mixed together. Many observers have found that normal human serum may clump when diluted to a strength of 1 in 10 or 1 in 20, and isolated cases are recorded where the serum in a strength of 1 in 40 has really clumped the bacteria. Great care must therefore be exercised when performing the test for diagnostic purposes to ensure that the blood is sufficiently diluted, in order that the error of the normal blood may be with certainty eliminated.

Collection and Dilution.—The serum may be conveniently collected from either the lobule of the ear or the finger. In either case the skin must be sterilised, the antiseptic removed and the part allowed to dry. The skin is then pricked, and the issuing blood collected in a small pipette. After the blood has coagulated, the serum is removed from the pipette and accurately diluted with sterile water, normal saline solution or broth, to the required degree, and mixed with a suitable quantity of bacterial emulsion. If a mixture containing 1 per cent. of the serum is required, it is customary to make a 2-per-cent. solution of the serum in broth or water, and then mix equal quantities of this and the bacterial emulsion in order to obtain the 1-per-cent. dilution. The undiluted serum should not be diluted with the bacterial emulsion, or the phenomenon of pseudo-clumping may be seen.

Demonstration of the reaction.—The agglutination may be observed either microscopically or macroscopically. In order to examine it microscopically, a loopful of the diluted serum is placed upon a clean cover-slip; after sterilisation, the same loop is filled with bacterial emulsion and a thorough mixture of the two fluids effected upon the cover-slip. This is then inverted upon a hanging-drop slide and examined with the microscope. After the lapse of a short interval—if the serum is going to agglutinate—small groups of bacilli will be found,

and these will grow larger, as time goes on, by the addition of more bacteria, until finally practically every bacillus in the original emulsion is in one of the now large clumps.

The macroscopic agglutination is seen if a small quantity—50 to 100 cubic millimetres—of the diluted serum and of the bacterial emulsion are mixed together in a watch-glass or small test-tube, and sucked into a fine, but not capillary tube, and one end of the tube sealed off. After allowing the tube to stand in a vertical position with the sealed end downwards for a few hours, the agglutination is evidenced by the fact that at the bottom there is a fine white flocculent precipitate, and the supernatant fluid is quite clear.

The reaction in Enteric Fever.—It must always be remembered that the agglutination-test is a quantitative and not merely a qualitative one. As has been previously stated, the serum of 30 per cent. of normal persons will show agglutination when in the strength of 50 per cent., and a considerable number are found to exhibit it in a dilution of 1 in 10; a few may show it in a dilution of 1 in 20, and an occasional person even in a dilution of 1 in 40. The great majority of enteric patients will, during some period of the disease, possess a serum which will agglutinate in a strength of 1 in 50, and not infrequently in much greater dilution (e.g. 1 in 200, 400, or even 800). It is necessary therefore to fix a *standard dilution*. Most clinical bacteriologists use the serum in a strength of about 1 in 20, and in practice this dilution gives an error of about 3 per cent. to 5 per cent.: the error shows itself in both ways; that is, enteric-fever patients may fail to show the reaction, and patients not suffering from enteric fever may give the reaction. A dilution of 1 in 50 will eliminate all the positive reactions from non-enteric patients and will probably eliminate none of the enteric patients who yield a serum which agglutinates in a dilution of 1 in 20.

As the actual agglutination occupies a certain time, and it is certain that the serum of some normal persons will show the phenomenon even when it is diluted, if left for many hours, it is also necessary to have a *standard reaction-time*. If a dilution of 1 in 20 be used, the reaction-time should be half an hour; if 1 in 50, an hour. If the mixture be examined under the microscope at short intervals, it will be found that a considerable proportion of reactions will take place in a few minutes, and the patients yielding these sera are, practically without exception, suffering from enteric fever, even if the dilution is only 1 in 20.

The day of the disease upon which the phenomenon first appears is very variable. Moreover, when the first sign of agglutination appears, it is so feeble that one is not able to use a sufficiently great dilution to differentiate it from normal serum. A reaction in a dilution of 1 in 20 may appear upon the third or fourth day, but this is rare; the usual time is about the eighth, ninth or tenth day; but it may not appear until the eighteenth, nineteenth or twentieth day, and very occasionally it never appears. In a dilution of 1 in 200, the reaction may rarely appear as early as the sixth or seventh day, but in quite a considerable proportion of the cases the serum will not react in this dilution during any period of the disease. There is, moreover, a distinct variation in the strength of the reaction in the same patient from time to time; on one day the serum may agglutinate in a strength of 1 in 400,

and three or four days later the highest dilution which will agglutinate is 1 in 100.

The question now arises 'What is the value of the test in the diagnosis of enteric fever?' The real answer to the question will depend upon whether a positive or negative reaction has been obtained. If a positive reaction has been obtained in a dilution of 1 in 200 within half an hour, the patient, without doubt, is suffering or has recently suffered from enteric fever. If the dilution is 1 in 20 the error may amount to about 1 per cent.

If a negative reaction has been obtained, the value of the observation will depend upon the day of the disease; one negative result early in the disease is of no value. If three or four examinations have been made at regular intervals, the last being upon the twenty-fourth or twenty-fifth day of the disease, and all with negative results, the error will amount to 1 or 2 per cent.; it is undoubtedly true that some patients suffer from a severe attack of enteric fever and die at the end of a fortnight or three weeks, who never give the reaction because the agglutinins are never formed. Although in the case of artificially immunised animals the serum of typhoid-immune animals may agglutinate the *B. enteritidis* of Gärtner, and Gärtner-serum agglutinates typhoid-bacilli in the human subject, this fallacy is practically negligible. The reaction may persist for a considerable time, even for years; care must therefore be taken to ascertain whether the patient has recently suffered from enteric fever. With these reservations the answer to the question may be summed up as follows. In from 97 per cent. to 98 per cent. of the cases, the presence or absence of agglutination will correctly diagnose whether the patient is suffering from, or has recently suffered from, enteric fever.

The reaction in Malta Fever.—What has been said of enteric fever and the *B. typhosus* applies to Malta fever and the *M. melitensis*. The disease is, like enteric fever, a chronic disease. In the case of Malta-fever patients, the serum is found to give a stronger reaction than generally obtains in enteric-fever patients, sometimes a dilution of 1 in 500 or 1 in 1,000 may agglutinate the micrococci. In performing the test the emulsion should be filtered through filter-paper in order to remove the clumps of cocci which are generally found in cultures of this bacterium.

The reaction in Glanders.—In man there are two distinct types of glanders, the acute and chronic. In the acute form the patient generally dies before the agglutinins are formed. In the chronic form, however, it is possible to use the test with advantage. The serum should be diluted to at least 1 in 100.

The reaction in Cholera.—The serum of patients who are recovering or convalescent from this disease usually shows agglutinative power, and the test may be applied to determine whether the patient has had an attack of genuine cholera; but for the diagnosis of the disease during an acute attack, the test is of course without value, since the patient will generally die or be on the road to recovery before the agglutinins are formed.

The reaction in Plague.—The remarks concerning cholera apply with equal force to this disease. In making the examination, the pseudo-clumps found in the cultures must be removed.

The reaction in Dysentery.—Quite recently a bacillus has been described in connection with

dysentery which is agglutinated by the serum of patients suffering from this disease; the reaction will therefore be, most probably, of considerable value as a diagnostic agent for dysentery.

WALTER C. C. PAKES.

SERUM-THERAPEUTICS.—There are two kinds of protective serums used in the treatment of disease, which possess different properties. The one kind is an *antitoxic* serum which neutralises bacterial and allied toxins, and the other is an *anti-bacterial* serum which hinders the multiplication of the bacteria in the tissues. Both kinds of serums are commonly, but incorrectly, designated antitoxins. The principal *antitoxic* serums are the diphtheria-antitoxin, the tetanus-antitoxin and antivenin; while the principal *anti-bacterial* serums are the anti-streptococcic, the anti-pneumococcic, the anti-plague, the anti-cholera, and the anti-typhoid serums.

These serums are specific in the sense that each one is only of use in treating the disease for which it is designed; the diphtheria-antitoxin, for example, is of benefit in the treatment of diphtheria, but has no effect upon a case of tetanus. Protective serums can be used either as prophylactic or as therapeutic agents. They are chiefly used in the latter capacity, as the protection they afford is of short duration, not lasting longer than two or three weeks.

METHOD OF ADMINISTRATION.—The serums are supplied either in the liquid or dried form. They cannot be administered through the alimentary canal, as they are destroyed during the process of absorption. They are accordingly administered by injection into the subcutaneous tissue. The site usually chosen for injection is the subcutaneous tissue of the flank. As a large quantity—about half an ounce—of serum is injected, special antiseptic precautions are necessary. The hands of the operator should be carefully cleansed with soap and water and afterwards with an antiseptic solution, such as carbolic acid (1 in 20) or lysol (2 per cent.). The skin of the patient at the site of injection should be treated in the same way. The syringe and needle should be boiled immediately before use and laid to cool upon a towel wrung out in an antiseptic solution. The cork and neck of the bottle containing the serum should be washed with an antiseptic before opening. The syringe is then carefully filled and the serum slowly injected into the subcutaneous tissue. A piece of antiseptic gauze washed in collodion is laid over the puncture. For each injection a fresh bottle of serum should be used. Many syringes have been designed for the injection of serum. The essential feature is that the piston and connections should be so constructed as not to be injured by boiling. For children it is advisable to connect the needle with the syringe by means of a short indiarubber tube, so as to avoid injury in the case of struggling.

If dried serum is used it must be dissolved in water which has been boiled and allowed to cool; and the solution should be made in a vessel which has been thoroughly cleansed with an antiseptic and subsequently rinsed with boiling water.

ILL-EFFECTS WHICH MAY FOLLOW ADMINISTRATION.—All therapeutic measures are attended by some risk, and the injection of serum comes under this category.

If the serum is contaminated, or if proper pre-

cautions are not taken during the process of injection, septic trouble may arise. Abscess at the site of injection occurred in 1·2 per cent. of the injections at the Metropolitan Asylums Board Hospitals, and one or two cases of death from septicæmia have been recorded.

Apart from these avoidable effects, symptoms sometimes of a serious nature may arise due to the introduction of an animal's serum into the human body, and analogous to the symptoms caused by the injection of the blood-serum of one animal into the tissues of another. In a few instances the administration of serum has led to immediate collapse which has even proved fatal. In several cases severe toxic symptoms, consisting of rigors, pyrexia, vomiting, convulsions, and rapid appearance of a rash have been observed. These serious symptoms are very rare, and only a few cases have been recorded among hundreds of thousands of injections.

Other symptoms not of a serious character more frequently arise. Rashes and articular pains, accompanied by pyrexia, constitute these symptoms. *Rashes* are observed in from 25 to 50 per cent. of the cases. They generally occur about the eighth day after the injection, but they may occur immediately after injection, or as late as the thirty-first day. The rash usually begins on the wrists and ankles, but it may start at the site of injection. It may be partial or may involve the whole of the body. In character the eruption is a blotchy erythema, looking like the rash of measles, or more rarely it is a diffuse punctate erythema similar to that of scarlet fever; it is often complicated with urticaria. With the rash there is malaise and pyrexia; the temperature may reach 104°, but is more frequently between 100° and 101°.

Articular pains are less common than rashes, occurring in about 5 per cent. of the cases. The hips, wrists, and ankles are the parts most frequently affected. There is seldom effusion into the joints, the pain and swelling being situated in the periarticular structures. The affection occurs at about the same time as the rashes, and is frequently accompanied by them and by pyrexia. In a few days the pain and fever subside.

Transient pyrexia, unaccompanied by rash or articular pain, sometimes occurs.

LIMITATIONS OF SERUM-THERAPY.—It has been shown experimentally that a much smaller quantity of serum is required to protect an animal when injected soon after infection than at a later period; and it has been found that after a certain time has elapsed no amount of serum however large is efficacious. Clinical experience bears out these observations: in the later stages of a disease the administration of serum is of very little value; the earlier the treatment is adopted the better the chance of recovery.

I. ANTITOXIC SERUMS. — Diphtheria-Antitoxin.—The value of serum-therapy has been more clearly established in the case of diphtheria than in any other disease. The reasons for this success are as follows. Diphtheria is a local disease in which the symptoms are caused by the slow absorption of toxins elaborated at the site of infection, and the anti-diphtheria serum contains an antitoxin, which, as can be shown experimentally, neutralises these toxins. The disease can be recognised by its local manifestations at an early stage before sufficient toxins have been absorbed to seriously damage the tissues. Detailed instructions concerning the

use and the efficacy of this serum in the treatment of diphtheria are given in the article on DIPHTHERIA, p. 407.

As a prophylactic, where there has been much exposure to infection, it may be considered advisable to administer antitoxin. For this purpose a dose of 200 units appears to protect for three weeks. The writer prefers to make daily bacteriological examinations of the throats of exposed individuals, and to defer using antitoxin until bacilli have been found, when a dose of 5000 units should be given.

Diphtheria-antitoxin does not keep indefinitely, but if placed in a cool dark place it will for practical purposes retain its potency for six months.

Tetanus-Antitoxin.—The toxin produced by the *Bacillus tetani* is a powerful nerve-poison. As can be shown experimentally, the anti-tetanus serum contains an antitoxin which neutralises the toxin. The tetanus-antitoxin is much more powerful than the diphtheria-antitoxin, but it is not so efficacious in human therapeutics. This is due to the fact that the disease cannot be diagnosed until the central nervous system has been severely affected by the toxins. It would appear that the antitoxin which has entered the circulation after subcutaneous injection is not capable of gaining access to the interior of the central nervous system. In accordance with this it has been shown that the intracerebral injection of antitoxin is more efficacious than subcutaneous injection in the treatment of guinea-pigs artificially infected with tetanus. The same method combined with subcutaneous injection has been employed for the treatment of tetanus in man. The dose for subcutaneous administration is 5 grams of dried serum or 10 to 20 c.c. of liquid serum, which should be given at first every 6 or 12 hours, and afterwards at longer intervals, according to the progress of the case.

Intracerebral Injection.—For intracerebral injection the dose is 2 or 3 c.c., the most potent serum being used. The method of administration is as follows: The patient is put under an anæsthetic, and the scalp over the front of the head is shaved and carefully sterilised. An imaginary line is drawn from one auditory meatus to the other, and another line from the base of the nose to the occipital protuberance. From the point where these two lines intersect a line is drawn to the outer angle of the orbit. The centre of this line is situated just in front of the motor convulsions and is the site chosen for injection. A hole is drilled in the skull at this site with a small Archimedean drill of a diameter a little larger than the needle of the syringe. The needle, which is about two inches long with a rounded point, is inserted into the brain as deep as it will go, and the serum is injected very slowly, about ten minutes being taken to inject the two or three cubic centimetres. The same operation is performed on the opposite side. During the operation careful antiseptic precautions must be taken, otherwise there is the risk of the supervention of cerebral abscess.

Efficacy of Treatment.—It is difficult to estimate the value of the treatment of tetanus with antitoxin. In some cases both after subcutaneous and after intracerebral administration the recovery of the patient seems to have been definitely due to the treatment. Subacute cases are more benefited than acute cases. It would appear advisable to combine the intracerebral injection with subcutaneous injection.

The liquid serum will keep in a cool and dark place without appreciable alteration in potency for several months, and the dried serum longer.

Anti-venomous Serum.—The principal constituent of the venom of poisonous snakes is a toxin which is a powerful nerve-poison, and which is identical in all species. In some species, in addition to the nerve-poison, there are other toxic substances which break up the blood-corpuscles and cause local inflammation.

Anti-venomous serum contains an antitoxin, analogous to the diphtheria- and tetanus-antitoxins, which neutralises the nerve-poison contained in the venom. This has been shown experimentally, and it has also been proved that the serum protects an animal when injected subsequent to the introduction of venom into the tissues. A number of cases of recovery, after treatment with serum, of patients bitten by poisonous snakes have been recorded. The dose is 10 to 30 c.c., which may be given subcutaneously, or better by direct injection into a vein. It should be administered as soon as possible after the bite, and the part affected should be treated in the usual way by proximal ligature and the injection of a solution of calcium hypochloride.

II. ANTI-BACTERIAL SERUMS.—**Anti-streptococcic Serum.**—There are many affections produced by the *Streptococcus pyogenes*, such as erysipelas, puerperal fever, and various septic conditions, in all of which the invasion of the tissues by the cocci is the essential factor of the disease. The anti-streptococcic serum does not contain an antitoxin, but it contains anti-bacterial substances which hinder the multiplication of the cocci in the tissues.

The potency of the serum hitherto prepared is not great when tested upon animals, and it has also been found that a serum which will protect against a streptococcus obtained from one source will not always protect against a streptococcus from a different source. The discordant results obtained in the treatment of cases in the human subject may thus be accounted for, especially when one remembers that the different serums in the market vary considerably in potency. Many cases treated successfully have been recorded, and there can be no question of its value in some cases; but we are still unable to say what cases will be benefited by the treatment. The treatment appears to have been most successful in cases of puerperal septicæmia. Sometimes when one brand of serum has been of no value another brand has proved efficacious.

The dose of anti-streptococcic serum is 10 to 30 c.c., which should be given two or three times a day in acute cases, and once a day in chronic cases. It is better to inject the serum near the site of infection if this is practicable. The serum appears to lose its potency if kept for more than a few months.

Anti-pneumococcic Serum.—Acute lobar pneumonia is by no means the only disease caused by the pneumococcus—pleurisy, empyema, meningitis, endocarditis and other affections may be caused by the same micro-organism. The anti-pneumococcic serum resembles the anti-streptococcic in containing anti-bacterial substances, but no antitoxin; and it acts in the same way, namely, by hindering multiplication of the cocci.

The potency of the serum supplied by Pane is such that 1 c.c. will protect a rabbit against 1,000 to 3,000 fatal doses of living cocci when injected simultaneously, but into different parts of the body.

Like the anti-streptococcic serum, a serum which will protect against one variety of pneumococcus will not always protect against another variety.

The value of the treatment of pneumonia with serum is still *sub judice*. We will only say that in some cases the treatment certainly appears to have been successful. The dose is from 10 to 20 c.c., which may be given twice a day until the fever has subsided. The treatment is applicable for any condition caused by the pneumococcus. The serum does not maintain its potency for more than four months.

Anti-typhoid, Anti-cholera, and Anti-plague Serums.—Serums have also been prepared against cholera, typhoid fever, and plague. They all contain anti-bacterial substances and no antitoxin, with perhaps the exception of the plague-serum, which contains a small quantity of antitoxin. We possess very little knowledge of the efficacy of treatment with these serums. They must not be confounded with the vaccines used as prophylactic against typhoid fever, plague, and cholera, and which have been improperly called serums.

J. W. WASHBOURN.

SETON, Use of.—A disused method of counter-irritation, consisting in the insertion of a tape or cord beneath the skin.

SHOCK.—SYNON.: Fr. *Choc*; Ger. *Shok*; *Wundstupor*; *Wundschreck*.

DEFINITION.—By the term 'Shock' is understood that condition of general depression of vital activity which follows upon a violent stimulation of the peripheral nerves or nerve-endings of the sensory or sympathetic system. It may also be produced by a sudden or severe emotion.

GENERAL DESCRIPTION.—As the result of a severe injury to a part richly supplied with nerves, such as the end of a finger, of laceration of a limb or large joint, or of a blow upon the abdomen, the subject is brought to a condition of general apathy. The surface becomes cold and clammy, the skin covered with perspiration, the aspect vacant yet anxious, the pulse feeble, the respiration weak, sighing, and irregular.

ÆTIOLOGY.—This condition may immediately follow the cause or may arise after an interval of more or less duration, as in the case of severe burns; here a state of excitement may give way suddenly to that of shock, which in such cases is generally followed by death. On the other hand, shock may be transient and may pass off rapidly, the intensity being generally determined by the nature, extent, and situation of the injury which brings it about. The effect is also largely dependent upon the mental and physical condition of the subject; other determining factors being age, sex, and habits. Any injury of even moderate intensity is much more serious in its effects upon the aged than upon younger and more robust subjects, and this in proportion to the evidences of senile degeneration. Children, on the other hand, resist the effects of severe injury, except in the case of severe burns or exposure to cold, far better than adults; while, on the contrary, operations upon the abdominal viscera are extremely hazardous in the very young on account of the supervision of shock even when the operation is in itself of comparatively slight gravity. Women, as a rule, bear severe operations better than men, but the effects of severe injury are more liable to produce disturbance of the nervous system, especially in the neurotic or hysterical.

The condition of the mind at the time of infliction of the injury has marked effect in determining the degree of shock. Thus, soldiers in battle are often unconscious of severe wounds until some time after their occurrence, but the depression that follows may be increased in proportion to the previous excitement. The same is true of emotional shock, where, as in the case of a criminal, the whole nervous system being in a state of the highest tension, a reaction follows on the pronouncement of the verdict, and a state of shock follows. *See* COLLAPSE.

Thus it is seen that shock is produced by injury occurring to parts most richly supplied with sensory nerves or viscera which are largely connected with the sympathetic system. The nature, extent and situation of the injury are important ætiological factors. Thus, crushing of a finger, blows upon the testicles, or injury to any of the abdominal viscera are among the most frequent causes. Burns, by reason of the large area involved and the consequent number of nerve-ends exposed, are most frequently followed by shock (p. 675). Formerly it was noticed that in amputations shock was found to occur when the medulla of a long bone was divided, or when in removal of a testis the

cord was cut through. But the more perfect knowledge of the art of anaesthesia has considerably reduced the frequency and the severity of such occurrences, though it has not abolished them entirely. Thus, it has frequently been observed that in patients only slightly anaesthetised, the division of the spermatic cord is attended by an immediate and sudden failure of the pulse, but that this does not occur when anaesthesia is complete (p. 61). The same is true in such major operations as amputation at the hip or shoulder, though collapse may follow as a result of haemorrhage. Cold or any previous condition which lowers vitality and leaves the nervous system depressed is naturally a predisposing cause. The temperament of the individual has to be taken largely into account, the so-called neurotic being much more prone to its occurrence than the robust and stalwart, while the alcoholic is a type that most frequently exhibits the results of shock in its most marked forms. When the whole nervous system is in a state of tension from expectation the liability to shock is far greater, while previous loss of blood by depleting the nerve-centres renders the patient much more susceptible than he otherwise would be. Subjects of organic disease, especially of the heart or kidneys, are more prone to exhibit the effects of shock, which in such persons is more severe and dangerous. Sharp injuries to tense fibrous structures frequently cause a sudden sense of faintness which is quite out of proportion to the damage done to the tissue. Thus a blow on the eye as from a spent pellet, or a kick upon the ankle or knee, may occasion a transient syncope often followed by a feeling of nausea. Blows upon the epigastrium cause a more lasting condition of the same nature, and the effects are occasionally so serious as to cause death.

PATHOLOGY.—The phenomena of shock are produced by the combined action of (1) the effect on the nerve-centres of massive sensory and sympathetic impulses from the injured part, by which the nerve-centres are exhausted. Though the sensory centres seem to be primarily affected, the closely connected motor areas are also involved. (2) Reflex action through the vagus, by which the heart is inhibited (at least temporarily), so that the blood-pressure rapidly falls. (3) Reflex action through the vaso-motor centre, so that the peripheral vessels are dilated, especially those of the splanchnic area, as a result of which the patient 'bleeds into his own vessels.' This also accounts for a fall of blood-pressure more lasting in effects than the vagus-action upon the heart.

The one striking phenomenon that is revealed, though not invariably, at *post-mortem* examinations of cases which have succumbed to shock, uncomplicated with excessive haemorrhage from the seat of injury, is an enormous distension of the abdominal vessels governed by the splanchnic nerves. Thus the abdominal viscera are engorged with blood destined for distribution over the rest of the system, and, as a consequence, the medulla and spinal cord are reduced to a state of feeble functional power, the first effects of which are shown in the action of the heart and the parts supplied by the vagus. This enfeebled action of the heart, and the scanty supply of blood which passes through its cavities, lead to a great reduction of the general vital activity and produce the symptoms which have been detailed. It has been shown by experiment that by stimulating the central

end of the divided depressor branch of the vagus in the rabbit, or striking the abdomen of the frog, the circulation can be profoundly modified by impulses that reach the vaso-motor centre, and the same result is probably produced in man by severe blows upon the epigastrium. Such procedures, by dilating the arterioles, and so lessening the peripheral resistance to the circulation, cause a fall of arterial blood-pressure more lasting than the vagus-action on the heart. Thus swallowing and all voluntary actions are impaired, though vomiting may herald a return of blood to the medulla. The temperature is lowered two or more degrees, though it may rise before death; the skin is moist, owing to vaso-motor changes, and the secretion of urine is suppressed. As defined by Mansell Moullin, 'shock is an example of reflex paralysis in the strictest and narrowest sense of the term, a reflex inhibition, probably in the majority of cases general, affecting all the functions of the nervous system, and not limited to the heart and vessels only.'

SYMPTOMS.—Whether it be due to injury, to emotion, or to exposure of nerve-ends over a large area or other cause, the occurrence of shock is rapid, though its advent may not be immediate, and may occur insidiously after some interval. It may vary in degree from a transient faintness to prolonged syncope or even death. In the slightest form the patient becomes pale and faint, often falling or clutching at the nearest object to prevent himself from doing so. The surface becomes cold and moist, beads of perspiration break out over the face and body, the hands are clammy, the pupils dilated. At the same time the muscles of the body are relaxed, the eyelids droop, the reflexes are slight. Consciousness is not absolutely lost, and questions are answered in a slow and feeble manner. There are 'all the evidences of general paresis of volition.' The pulse at first is slow, weak, and often dicrotic, with a tendency to become frequent, irregular, and imperceptible. The respirations are feeble, sighing, and shallow. The temperature is always low, often falling as much as two, three, or even more degrees. The expression is vacant. These conditions are more or less marked according to the severity of the cause and the temperament of the individual. The situation of the lesion has important bearing upon the effect produced, a small wound of the intestine producing much more severe consequences than extensive injury to a limb. The same conditions govern the duration of the symptoms. These may last from a few minutes to several hours before reaction commences. This is often heralded by an attack of vomiting due to a hyperemia of the nervous centres which follows the previous abstraction of their blood-supply. After this the pulse gradually becomes rhythmic and fuller, pallor gives place to a flushed colour, and the senses gradually recover, though a feeling of weakness remains, often for a considerable period. On the other hand, the symptoms may increase in severity notwithstanding all treatment, the pulse and respiration becoming more feeble and imperceptible until death occurs.

Travers described shock as occurring in two forms: (1) with great prostration, in which the symptoms are those just described; (2) with exhaustion followed by traumatic delirium. This is sometimes termed *erethitic* or *erethistic* shock, but is not so frequently observed now that the art of anaesthesia is better understood (p. 63). It may, however, occur as a sequel to the former condition, especially

after major operations, or in association with previous hæmorrhage; or when there is great pain, as in crushing injuries of important parts, or after burns or scalds. It is marked by great and increasing restlessness; the consciousness may be but little impaired, but questions are scarcely heeded, and traumatic delirium is a frequent sequel. It is probable that this condition is due to the introduction of a toxic element.

'Railway shock' is a form of traumatic neurosis which may develop immediately or even many weeks after an accident to a train, from which the individual may have experienced no manifest sign of injury (*see* RAILWAY INJURIES). Headaches and a feeling of lassitude are first complained of, and these are followed or accompanied by sleeplessness and nervous irritability. The mental attitude is altered, the patient becomes despondent, and symptoms of melancholia develop. Often there is numbness and tingling in the extremities, and the reflexes are increased as in ordinary neurasthenia. Some cases may have marked hysterical features, or symptoms that suggest organic disease of the brain or spinal cord. Bladder-troubles and signs of sclerosis of the cord may be well marked. The muscular powers of the limbs are enfeebled, the circulation becomes weak, the intellect dull, and the general health deteriorates. These conditions may progress until the patient dies in a condition resembling general paralysis. The anatomical changes are not definite. The brain and spinal cord have sometimes exhibited punctiform hæmorrhages; and arterio-sclerosis of the vessels, with scattered areas of degeneration in the white substance, has been observed, as well as degeneration of the sympathetic ganglia. Although death may not be directly due to this cause, and although a perfect recovery may ensue, yet a deterioration of health is the usual sequel, or some impairment of a special sense, or the mental vigour and temper of the individual may be changed for the worse.

DIAGNOSIS.—This must depend to a great extent upon the nature of the cause and the situation and character of the injury. Where no lesion has occurred and where mental emotion is the only cause of the symptoms there is no question of the nature of the condition. Generally the distinction between shock and collapse is not distinctly marked, the one occurring preliminary to the other (*see* COLLAPSE). In the case of wounds, shock is followed by collapse as the result of loss of blood. In severe injuries attended by excessive hæmorrhage the collapse is mainly due to the loss of blood. Thirst, restlessness, and dyspnoea are then the predominant symptoms, together with the rapid but feeble and easily compressible pulse. The mental condition is little affected except that it evinces great irritability and excitement, which do not quickly subside. In the case of rupture or perforation of the intestine shock precedes collapse, which occurs as the result of peritonitis due to the absorption of toxic elements.

Uncomplicated shock, except in cases of very severe injury, tends towards recovery; collapse, on the other hand, is much more likely to be fatal. Shock differs from syncope in that the prostration is much more prolonged, and consciousness, though blunted, is not abolished. In head-injuries the symptoms of concussion (p. 335) are not necessarily accompanied by those of shock. The senses are almost or completely dulled, but there is not gene-

rally the same blanching of the surface, or the utter prostration which is manifested in shock, nor is there a fall of the temperature to the same extent. The two conditions may, however, co-exist. The state of the pulse will generally indicate the difference, being slow, full, and regular in direct injury to the brain; faint and irregular in cases of shock. Where there is internal hæmorrhage it is often impossible at first to distinguish the conditions, but the advent of syncope and the absence of reaction, together with the nature and situation of the injury, will soon show the predominant features. A faint condition with pallor often precedes vomiting in patients under the influence of an anæsthetic, and is recovered from as soon as vomiting has taken place, when the anæsthesia may be continued.

PROGNOSIS.—This depends mainly upon the nature and extent of the injury, and upon the physical and mental powers of the individual. The longer the condition of shock endures, and the lower the fall of temperature, especially if it sinks below 96° F., the more unfavourable is the outlook, and the prospect becomes graver the longer reaction is postponed.

The question of operation during the continuance of shock must be judged by individual cases. As a general rule it is the practice of surgeons to wait until signs of reaction have appeared; but where it is evident that the injured portion is maintaining the condition, or where bleeding is evidently proceeding, there is no reason to delay. In such cases an anæsthetic should be given, and for this purpose ether is clearly indicated (p. 61), since by its stimulating effects upon the action of the heart it relieves the anæmia of the medullary centres, and as the pulse improves under its influence the effects of injury to the nerve-ends are greatly palliated.

TREATMENT.—A consideration of the causes and conditions obtaining in shock is a sufficient indication as to the lines of treatment to be followed. In slight cases very little is required except to place the patient in a recumbent position and apply some aromatic stimulant, such as ammonia, to the nostrils. In more severe or prolonged conditions the patient must be kept recumbent, with the head at a lower level than the feet. Warmth is the essential to overcome the vaso-motor paralysis, and therefore the temperature of the room must be maintained at between 80°-90° F. Hot-water bottles or hot bricks wrapped in flannel should be applied to the feet and sides of the body. Very hot fomentations placed over the præcordia and on the nape of the neck are most effectual in stimulating the heart's action. Where possible the patient may be placed in a hot bath at a temperature of 104°, gradually rising to 110° F. The pulse and respiration must be carefully watched, and in desperate cases the phrenic nerve may be stimulated by the galvanic battery, the poles being placed along its course in the neck and over the epigastrium. If swallowing is possible small quantities of brandy, or, at a later stage, strong black coffee, should be given; but where this is not feasible subcutaneous injection of ether or of strychnine must be given and repeated at intervals. Where there has been excessive hæmorrhage injections of hot water and brandy into the rectum, or the transfusion of normal saline solution into the veins of the arm, should be resorted to without delay (*see* SALINE SOLUTION, Infusion of). Though not admissible in the torpid

form of shock, in the state of excitement small injections of morphine should be given and an ice-coil applied to the head. The temperature and pulse must be carefully watched for any indication of inflammatory reaction, and the treatment regulated accordingly. The greater the effect produced the greater must be the care in the subsequent treatment of the case. The eyes must be protected from light, and all excitement must be avoided for many days. Belladonna to stimulate the heart's action, or opium to quiet the nervous system, must be sparingly used. *See* also HEAT, Effects of Severe or Extreme, p. 676.

SIALAGOGUES (*σίαλον*, saliva; and *ἄγω*, I move).—*SYNON.*: *Fr.* *Sialagogues*; *Ger.* *Speicheltreibende Mittel*.

DEFINITION.—Remedies which increase the secretion of saliva.

ENUMERATION.—The principal sialagogues are Dilute Acids, Ether, Ginger, Rhubarb, Horseradish, Iodide of Potassium and other iodides, Jaborandi, Mezeoron, Mercury and its salts, Mustard, Tobacco, Physostigmine, Pyrethrum, and Pebbles.

ACTION.—There are two essential factors in the secretion of saliva: the first is the activity of the secreting cells in the gland; the second is a sufficient supply of nutritive material to them, from which they may form a secretion. This nutritive material, though it may be derived directly from the lymph-spaces around the cells, must be ultimately supplied by the blood circulating through the glands. Usually, therefore, when the gland is in action, the supply of blood is greatly increased, the arteries dilating, and the blood flowing rapidly through them. Some drugs, such as physostigmine, will stimulate the secreting cells, while they contract the blood-vessels; under these circumstances, although the secretion may begin actively, it soon comes to a standstill from want of material. The secreting cells may be excited to activity by substances which stimulate the nervous structures within the gland itself, as, for example, Calabar bean (physostigmine); by stimuli proceeding directly from the encephalon, as seen in salivation occurring from the mere idea of savoury food; and by stimuli applied to the mouth and exciting the gland reflexly. Nausea is almost always accompanied by salivation, and substances which cause nausea almost invariably cause salivation, the irritation of the stomach causing reflex salivary secretion. The stimulus here passes up the afferent nerves to the medulla, and travels down the efferent nerve to the gland.

Sialagogues are divided, according to their mode of action, into two classes—(1) *topical or direct*; and (2) *specific, remote, or indirect* sialagogues. The names *direct* and *indirect* are complete misnomers, just as they are in the case of emetics, and they ought to be discarded, inasmuch as the so-called 'direct' sialagogues are those which do *not* act

directly on the gland, but on the mouth; and the 'indirect' are those which do act upon the gland, affecting either the nervous structure contained within it, or the nerve-centres directly connected with it.

The *topical* sialagogues are dilute acids, ether, ginger, rhubarb, horseradish, mezeoron, mustard, pebbles, pyrethrum, and tobacco. The *remote* sialagogues are iodide of potassium and other iodides, jaborandi, mercury and its salts, physostigmine, and tobacco.

Topical sialagogues excite secretion of saliva reflexly, the afferent nerves being the lingual and buccal branches of the fifth, and the glosso-pharyngeal nerves. The afferent nerves, through which nauseants probably excite the salivary secretion, are the vagi.

Of remote sialagogues, iodide of potassium probably acts upon the gland-structures, but upon which part has not yet been determined. It may, however, also act reflexly, by stimulating the sensory nerves of the mouth, as it is excreted in the saliva, and the taste of it is often persistent. Mercury probably acts partly by affecting the gland-structures, and partly by affecting the mouth. Jaborandi, physostigmine, and tobacco appear to affect the terminal branches of the secretory nerves in the glands.

USES.—Saliva is useful in keeping the mouth moist, and thus facilitating mastication, deglutition, and the movements of the tongue in speaking. By moistening the fauces it also prevents or lessens thirst. A pebble placed under the tongue, or masticated, or an effervescent lozenge, will keep up a slight flow of saliva, and may be useful for these purposes. Where this is insufficient, dilute acids are employed (*see* ACIDS). As the flow of blood to the glands is greatly increased during secretion, sialagogues, and especially pyrethrum, have been used as derivatives, to lessen inflammation, congestion, and pain in other parts of the head, as in toothache, earache, and inflammation of the ear, nose, or scalp. Saliva has also, however, a digestive power upon starch, and increase of the flow may be advantageous in imperfect digestion of this substance. When swallowed, the saliva stimulates the secretion of gastric juice, and increased salivary secretion therefore tends to aid gastric digestion. To attain this object it is best to chew a piece of ginger or of rhubarb.

Dryness of the mouth and tongue, especially on awakening in the morning, often arises from breathing through the mouth in consequence of nasal obstruction. In such cases treatment of nasal congestion and removal of obstruction such as adenoids are more useful than sialagogues.

T. LAUDER BRUNTON.

SIBILANT RÂLE or RHONCHUS: SIBILUS (*sibilus*, whistling).—A variety of dry *râle* or rhonchus, of a whistling or high-pitched musical character, usually produced in the smaller divisions of the bronchi. *See* PHYSICAL EXAMINATION; and RHONCHUS.

SICILY.—A warm, moist, winter climate. Climate of base of Etna more variable than of N. coast. *See* CLIMATE, Treatment of Disease by; and PALERMO.

SILICOSIS.—See PNEUMOCONIOSES.

SINGERS' NODES.—See p. 853.

SINUS and FISTULA. — DEFINITION. — A track leading from a surface into the tissues and ending blindly is called a *sinus*. When the track passes from one surface to another, or from one part of the same surface under a bridge of tissue to another part, it is called a *fistula*.

ÆTIOLOGY.—The chief conditions which give rise to sinuses and fistulae are the following: (1) *Congenital defects*: tracks due to these may be present at birth, or may form in later life; (2) *Wounds*; (3) *Abscesses*, which burst on one or two surfaces, leaving a track which does not close; (4) *Ulceration* through a natural septum, or through a partition formed by the adhesion of separate structures, as of the intestine to the bladder; (5) *Sloughing* of a portion of the wall of a channel or cavity; (6) Infiltration of the wall of a hollow viscus, or of the tissues separating two such viscera, by *new-growth*, with subsequent degeneration and breaking down of the tumour.

The natural tendency of any pathological channel formed in the tissues is to close up and become obliterated. A variety of causes may, however, prevent this, and so lead to the formation of a sinus or fistula. Thus (a) imperfect drainage of a cavity may cause retention of discharge, which may burst out at intervals as the tension rises; (b) Traumatism, gangrene or ulceration may have destroyed so large an amount of tissue that the healing process cannot make good the gap; (c) When union has been long delayed, owing to constant drainage of some secretion or excretion through a track, epidermis may grow in from the surface and form a lining to the tube, thus preventing the possibility of spontaneous obliteration; (d) A foreign body, a sequestrum, or a caseous gland may keep up a discharge for an indefinite period; (e) The wall of the channel may be formed of unhealthy tissue—tuberculous or cancerous—and show no tendency to undergo repair; (f) Continual movement of surrounding muscles may disturb that rest of the part which is necessary for the occurrence of healing.

A common variety of sinus is that seen in connection with chronic disease of bone, due to tubercular or pyococcal infection (acute necrosis). Such a sinus is practically a tubular ulcer. It is lined by granulation-tissue, which is irritated by constant passage of the discharge and by the presence of septic organisms. Examples of fistulae are seen in cases of remnants of branchial clefts in the neck; a 'fistula in ano,' in which a track is found passing beneath the mucous membrane of the anus and opening both externally below and into the gut above; and in cases of vesico-vaginal and recto-vaginal fistulae, caused by injuries inflicted in parturition or by the

involvement of the tissues separating the cavities in masses of malignant growth.

DIAGNOSIS.—When a sinus or fistula opens on to or near the external surface of the body, its nature is readily determined by the eye or by the use of a probe. The opening may be very minute and need careful search. When the orifice is out of sight, the presence of a fistula may be revealed by the escape of abnormal material from a cavity, as of urine from the rectum, or of gas and feces from the urethra.

TREATMENT.—Cure of a sinus or fistula may often be effected by laying it open throughout and plugging the cavity, which then heals from the bottom by granulation. A careful watch must be kept to prevent premature union of the edges. If the condition be chronic, the fibrous wall of the track must be cut quite through on its deep aspect; it is still better to excise the whole track. Excision must also be practised in cases of congenital sinuses and fistulae which are lined by epithelium. Closure of the wound by 'purse-string' sutures sometimes brings about speedy union. Any foreign body, sequestrum or tubercular focus must be removed. Malignant fistulae can rarely be dealt with; excision of the growth and suture of both openings has been performed. In many cases of fistula complicated plastic operations are necessary to effect a cure.

STANLEY BOYD.

SINUSES, CEREBRAL, Diseases of.—See MENINGES, Diseases of.

SINUSES, NASAL, Diseases of.—See NOSE, Diseases of.

SIXTH NERVE, Diseases of.—The sixth nerve, or *abducens oculi*, confers motor power on the external rectus muscle of the eyeball, and its morbid states of excessive or defective function are indicated by corresponding spasm or paralysis of that muscle.

1. **Spasm of the external rectus.**—This condition is very rare, except in myopia, in which an effort at accommodation is needless, and the associated action of convergence is also unnecessary. Hence the muscles causing divergence act in relative excess. Permanent contraction occurs when there is complete paralysis of its antagonist, the internal rectus. Spasm may occur from irritation of the nucleus or fibres of the sixth nerve, as in meningitis of the base. The symptoms are inclination outwards of the affected eye, and consequent divergent strabismus. The treatment is that of the cause on which it depends. See STRABISMUS.

2. **Paralysis of the external rectus.**—**ÆTIOLOGY.**—Among common causes are tumours, and other lesions within the pons, and various forms of syphilitic disease. The latter may cause a specific growth on the nerve, or damage it by inflammation and compression by the new tissue which is so abundantly formed in syphilitic meningitis. The nerve suffers also in other forms of meningitis with great readiness, on account of its long course, which renders it liable to be involved in various regions of the base, and to be affected more frequently than any other cranial nerve. Its course over the convexity of the pons involves a liability to suffer from any cause, such as a tumour, which increases the pressure beneath the tentorium. Hence tumours of the base of every kind are frequent causes of its paralysis. It suffers also from

disease in the anterior part of the base, at the orbital fissure, and within the orbit, when the nerves to other ocular muscles are usually also involved. Isolated neuritis, due to cold, is a rare cause. It may also be paralysed in tabes, with or without other nerves to the ocular muscles.

SYMPTOMS.—Paralysis of the external rectus causes inability to move the affected eye outwards, and hence convergent strabismus, and homonymous diplopia when looking at an object on the affected (e.g. left) side of the middle line, the images becoming more distant as the object is moved to the left; but parallel, and on the same level, so long as it is on the horizontal plane. When looking also up or down, the second image slants, the two being nearer together at the lower end, and the second image the lower of the two when looking up. On looking down, the two images are nearer together at the top than at the bottom, and the second image is on a higher level than the other. There is erroneous projection of the field of vision, so that the hand is moved beyond an object on the side which an attempt is made to touch—the muscular effort being guided by the increased innervation. There may be for a time a tendency to giddiness when the affected muscle is used.

DIAGNOSIS.—Paralysis of the sixth nerve is easily recognised, except when slight in degree. In the latter case it may often be detected by a careful search for the diplopia, or by the secondary deviation of the sound eye in the same direction when that eye is covered and an object fixed by means of the weak muscle. See STRABISMUS.

PROGNOSIS.—The prognosis is most favourable when the paralysis is due to cold or syphilis; least favourable when due to meningitis or tumour. When associated with ataxy recovery is common, but is often followed by a relapse, which frequently does not entirely pass away.

TREATMENT.—When the complaint is of rheumatic origin, the treatment should consist of hot fomentations to the temple; afterwards counter-irritation by blisters; and salicylates, with small doses of mercury and tonics internally. If of syphilitic origin, iodide or mercury should of course be given.

For the palsy associated with tabes strychnine and arsenic may be employed. The use of electricity in any form or mode of application is without appreciable influence. For the palsy which is part of external ophthalmoplegia, the hypodermic injection of strychnine gives the best results in cases that are not of too long duration.

SKIN-BOUND DISEASE.—A popular synonym for sclerema neonatorum. See SCLEREMA NEONATORUM.

SKIN-GRAFTING.—Skin-grafting consists in the transplantation of portions of skin of varying size and thickness from a healthy part of the body of the patient himself, or of some other person or animal, on to a recently made raw surface or a granulating sore.

Skin-grafting thus differs from a plastic operation, which involves the shifting of a flap of skin and subcutaneous tissue from one part of the body to another, without completely dividing its vascular connections with contiguous parts.

METHODS.—Several years ago Reverdin introduced the plan, which might more properly be

called epidermis-grafting, of placing minute portions of the superficial layers of the skin, containing, however, the cells of the *rete Malpighii*, on a healthy granulating surface, to which they adhered and served as the starting-points for the spread of epidermis over it. The grafts were shaved off from any healthy part of the skin with a sharp knife, the incision being barely deep enough to draw blood. They were then placed, with the deep surface downwards, on the sore, and not very far from one another, as each graft does not, as a rule, grow readily to a larger size than that of a sixpenny-piece. It is presumed that in all operations of skin-grafting close attention will be paid to keeping both the graft and the sore aseptic, the way of accomplishing which will be given in a later paragraph. Neglect of this precaution exposes the grafts to the irritating influence of putrefaction, which much endangers their vitality.

More recently Thiersch has brought forward a great improvement on this method. It consists in shaving off with a broad razor or special knife a strip of the superficial parts of the skin (as in Reverdin's plan, going just deep enough to draw blood, but no deeper) one inch wide and of any required length, and preferably from a part where the skin can be easily made tense by grasping the opposite side of a limb, such, for example, as the anterior surface of the thigh or the outer side of the arm. This strip is either laid on the raw surface entire, or is cut into pieces half an inch or more long, which are to be placed quite close together over the granulating or raw surface. If the former, the superficial granulations must be previously scraped away, so as to remove any irregularities and leave behind only a material which, though highly vascular, is little prone to contract, because it has already contracted as much as is possible. The grafts must not be placed in position until all bleeding has stopped, and this result may be encouraged by exerting pressure with a sponge over a piece of some smooth material, such as oiled-silk protective, placed upon the wound.

Watson Cheyne has more recently still recommended that the whole thickness of the skin should be used for the grafts. This has the disadvantage that contraction must occur in the part from which the graft is removed, but the advantage that it is reduced to a minimum in the part to which the graft is transplanted. It should certainly be adopted in cases such as excisions of the mamma, where a piece of redundant skin from the axilla may be used to fill a gap between the flaps on the front of the chest. The deep surface of the graft may be prepared by chipping off, with a sharp pair of fine scissors curved on the flat, any pieces of fascia or fat remaining adherent to it.

PRECAUTIONS.—In performing the operation, the part from which the graft is to be taken must be purified by shaving it and washing it thoroughly with a solution of carbolic acid (1 : 40), of corrosive sublimate (1 : 1000), or probably the desired result would be obtained by using simply alcohol mixed with 25 per cent. of water. If any time is to elapse between its removal and its application to its new seat, it may be kept in a sterilised saline solution heated to the temperature of the body. If it is to be placed on a surface which is already septic, this must be prepared by the application for a few days of a moist antiseptic application frequently changed, say boric lint soaked in a 1 to 2000

sublimate solution; and it is often well to begin this treatment by purifying the skin with 1 to 20 carbolic-acid lotion, and the sore with a solution of chloride of zinc, 40 grs. to 1 oz. A piece of oiled-silk protective should be placed on the grafts before the antiseptic dressing, whatever it may be, is applied. Care must be taken to prevent the edges of the grafts from turning over. If the grafts be not placed close together, lines of granulations may form between them, and much interfere with the presentableness and stability of the scar.

Some surgeons have obtained the grafts from the skin of frogs and other animals, but we have not sufficient knowledge yet to speak positively in recommending this plan. The skin of the prepuce has also been used for the purpose. The best and safest source of supply is undoubtedly the skin of the patient himself, for it has happened that both tuberculosis and syphilis have been transmitted when the graft has been taken from another person.

In *plastic operations* a flap of skin and subcutaneous tissue decidedly larger (as three to two) than the surface to be covered is turned up from some contiguous or distant part, but left attached by a sufficiently wide base to ensure its retaining its vitality. The flap is then shifted round and secured by sutures to the raw surface, which it must accurately fit. If the part from which it is to be transplanted be at some distance from that to which it is to be adapted, the part on which the latter is situated must be firmly secured in position until the flap has formed its new connections, when the pedicle is to be divided, and the part to which it has now become adherent is allowed to assume its natural position.

RICKMAN J. GODLEE.

SKIN, Tuberculosis of the.—It is only of late years that the group of cutaneous tubercloses (tuberculodermiae) has been constituted and consolidated from among the affections included under the terms Tubercular Ulcer, Lupus, Scrofulodermia, &c. Virchow taught that the skin was refractory to tuberculation, and possibly the more superficial layers from reasons of anatomical structure or temperature are so; but, however that may be, tuberculosis of the skin is of frequent occurrence, and characterised by a great diversity of features dependent on the virulence and quantity of the bacillus and its products, the quality of the soil, the mode of origin, the anatomical characters of the site involved, and the complications supervening. The skin may be so affected at any age, but children and adolescents are especially prone. Not infrequently the subjects present characteristics which, experience teaches us, mean a vulnerability of the tissues and a susceptibility to tubercular infection. Such features are a feeble peripheral circulation, a quality of skin sometimes portrayed in the 'lymphatic facies,' and a liability to chronic catarrhs of mucous membranes and of the skin with pus-formation. Further, the presence of a special susceptibility may be inferred from the history of tuberculosis in the family or the antecedents of the patient; or tuberculosis may be actually present in some other tissue. Yet often the subjects are apparently quite healthy, and the inoculation may be traceable to the special risks of their surroundings.

The criteria by which the tubercular nature of a skin-lesion is determined are: (1) the clinical features (morphology and infective character) which experience has taught us; (2) the characteristic

pathological changes in the tissues; (3) the presence of the special bacilli, which, however, may be few in number or temporary, and thus difficult to find; (4) the transmission of the disease by the serial inoculation of morbid products into certain animals when proper conditions are fulfilled; (5) the reaction to Koch's tuberculin.

The orderly arrangement of the diverse clinical manifestations which conform to these criteria is not easy, but for clearer exposition it will perhaps be convenient to retain for the present certain distinctive terms, viz.: (1) *verrucose tuberculosis* of Riehl and Paltauf, including the so-called *verruca necrogenica* (S. Wilks), or *post-mortem wart*; (2) the *primary tubercular ulcer*; (3) the *secondary granular tubercular ulcer*, '*tuberculosis propria seu miliaris*' (Kaposi); (4) *Lupus tuberculosus* vel *L. vulgaris*, with its diverse modifications; (5) the *tubercular gumma*; (6) the so-called *Scrofulodermie*; (7) '*Tuberculides*.'

Certain *paratuberculides*, such as pigmentary disturbances, which may occur in association with tuberculosis, will not be further referred to here. *Lupus erythematosus* is also included under cutaneous tuberculosis by some authors.

Lupus vulgaris.—Lupus is a figurative term, which was applied to diverse affections, and, although Willan's definition limited the application of the term, it is only in late years that the tubercular nature of the disease has been definitely established. It is the most common and characteristic reaction of the skin to the direct inoculation of the tubercle-bacillus, and must be considered as the type, but both in the skin and mucous membranes it differs markedly in its symptomatology from the miliary tubercular ulcer of the tongue and muco-cutaneous orifices. It may arise at any period of life, but with especial frequency in childhood and adolescence (75 per cent. before the age of twenty), and nearly twice as often in girls as in boys.
